## Dissertation abstract

Lake sediments are some of the best archives of continental climate change, particularly in the tropics. This study is focused on three ~10m sediment cores and high-resolution seismic reflection data from Lake Turkana in northern Kenya. Lake Turkana is the world's largest desert lake and the largest lake in the Eastern Branch of the East African Rift System. It is situated at ~2 °N at 360 m elevation and is ~250 km long and ~30 km wide with a mean depth of 35 m. The lake surface receives less than 200 mm yr<sup>-1</sup> of rainfall during the twice-annual passing of the Intertropical Convergence Zone via Indian Ocean-derived moisture, and evaporation is >2300 mm yr<sup>-1</sup>. This study is the first to quantify the climate and deepwater limnologic changes that have occurred in the area during the African Humid Period (AHP) and since the Last Glacial Maximum.

A 20-kyr, multiproxy lake level history was derived from ~1100 km of CHIRP seismic reflection data, in conjunction with gamma ray bulk density, magnetic susceptibility, total organic carbon, total inorganic carbon, core lithology, and scanning XRF data from sediment cores that were chronologically constrained by radiocarbon dates. Two desiccation events occurred at 18.5 and 17 ka when the lake was at least 100 m lower than today, as evidenced by basin-wide, high-amplitude reflections correlated to sand intervals in the sediment cores. Lake level rose abruptly at ~11 ka as interpreted from an increase in organic carbon content and abrupt shift to silt and clay-sized sediment, after which Lake Turkana overflowed into the White Nile River System. AHP highstand conditions lasted until ~5 ka when the lake became a closed basin. The loss of Lake Turkana as a White Nile input likely had significant implications for nascent communities living along the Nile. Lake level has fluctuated but remained at a moderate lowstand since its mid-Holocene closure.

An easterly shift of moisture derived from the Congo Basin has been proposed as an additional moisture source for environments in East Africa during the AHP, as evidenced by an expanding number of hydrogen isotope records from lake basins in East Africa. To determine if Atlantic-derived moisture reached Lake Turkana in the past via the Congo Basin, compound specific ( $C_{28}$  *n*-alkanoic acids) hydrogen isotopes ( $\delta D_{wax}$ ) were measured from the composite sediment core record from Lake Turkana.

The record revealed that  $\delta D_{wax}$  values were depleted by more than -60‰ during the AHP.  $\delta D_{wax}$  depletion occurs abruptly at 13.7 ka and is sustained throughout the AHP, and values gradually become more enriched after 7 ka. This depletion suggests that Congo-derived moisture had a significant influence on Turkana precipitation during the AHP, but depletion of that magnitude cannot be explained solely by a change in moisture source. In addition to the source effect, a possible vegetation effect was quantified using stable carbon isotopes of leaf waxes, and the amount effect was estimated using modern Kenyan amount effect coupled with a published basin fill model. It was determined that vegetation can account for up to -17‰, and amount effect estimations range from -17‰ to -24‰ of the total AHP depletion. After accounting for these effects, precipitation during the AHP is depleted relative to a 100% increase in precipitation amount, which we suggest is driven by an influx of moisture derived from the Congo Basin. Our calculations suggest that at least 45% of the moisture supplied during the AHP was Congo-derived.

The precipitation-evaporation balance of a lake system is closely related to its heat budget. To quantify changes in temperature through the onset and termination of the AHP, the paleotemperature proxy called TEX<sub>86</sub> was used to generate a 14-kyr record of lake

surface temperatures for Lake Turkana. This proxy has successfully reconstructed regional and high-latitude paleotemperatures in other large African lakes.

TEX<sub>86</sub> temperatures from 14 to 0.4 ka are highly variable and range from 24.3 °C to 28.6 °C with a mean of 25.9 °C. There is a long-term trend within the temperature record that follows mean northern hemisphere peak summer insolation, and a mean temperature of 26.2 °C during the early Holocene decreases to 25.7 °C during the late Holocene. A century-scale fluctuation of ~1 °C persists throughout most of the record which appears to be related to lake mixing processes that overprint the regional climate signal based on fluctuations in metal ratios. While this reduced sensitivity of the TEX<sub>86</sub> proxy was an unexpected result from this analysis, it has shown that this proxy may have limitations in its application to well-mixed, tropical, arid-land lake systems. Despite high-frequency variation, TEX<sub>86</sub> temperatures remain close to the mean for the duration of the record, which is attributed to the evaporation response of this lake system.

STRATIGRAPHIC FRAMEWORK AND QUATERNARY PALEOLIMNOLOGY OF THE LAKE  
TURKANA RIFT, KENYA

## **Acknowledgements**

This work could not have been accomplished without the support and guidance of Chris Scholz, my advisor, to whom I am grateful for bringing me to this program and encouraging me to stick around for a few extra years to see what else I could learn about Lake Turkana. I also appreciate the guidance from and accommodation by Jim Russell and Bruce Wilkinson and the rest of my committee.

I would like to thank my parents and my sister for being patient and supportive from halfway across the country, and Joe from halfway across the Pacific Ocean. I would like to thank Pete and Jacki, both of whom have been nothing but helpful for the last five years. The rest of the members of the Department of Earth Sciences have also played necessary roles in my completion of this degree.

Most of all I want to thank the friends that I have made while being in Syracuse. They have acted as my family and have encouraged me without obligation throughout this entire process. Alina, Aaron, Joe, Melissa, Jen, Matt, AnneMarie, and Ed, I truly cannot thank you enough.

## **Preface**

East Africa is one of the most climatically diverse regions in the world. The influence of moisture sources and precipitation delivery systems have shifted through time due to changes in orbital parameters and the accompanying climatic feedbacks. Lake Turkana is a unique study area in that it is at one of the lowest inland elevations on the African continent. Its degree of aridity results in quick changes in precipitation and temperature. Lake Turkana is also part of the Nile River drainage when the lake is at highstand, and likely played an important role in both historic and prehistoric times for nascent communities and animal populations in the Nile Valley.

This project was designed to determine timing of transitions between humid versus arid climates in the late Quaternary of East Africa as well as changes in temperature as derived from the sediment record and proxies generated therein. The work was divided into three parts:

**Chapter 1:** Stratigraphic framework and lake level change in Lake Turkana over the last 20 ka. This chapter set the groundwork and sedimentological basis for the rest of the project. Seismic sequences were developed and analyzed in conjunction with Kullenberg sediment cores to develop a lake level history and general climatic context for Lake Turkana since the Last Glacial Maximum.

*Published as:* Morrissey, A. and Scholz, C.A., 2014, Paleohydrology of Lake Turkana and its influence on the Nile River system: Palaeogeography, Palaeoclimatology, Palaeogeography, v. 403, p. 88-100.

**Chapter 2:** Paleoprecipitation analysis as derived from compound-specific hydrogen isotopes of leaf waxes through the African Humid Period. A  $\delta D_{\text{wax}}$  record was generated from sediment cores to determine both amount and sources changes in precipitation through time.

*To be submitted as:* Morrissey, A., Scholz, C.A. and Russell, J.M., Late Quaternary atmospheric circulation over the Turkana Rift, East Africa to *Earth and Planetary Science Letters*.

**Chapter 3:** Temperature variation was analyzed using a high-level organic carbon lake surface paleotemperature proxy called TEX<sub>86</sub>. Lake surface temperature is sensitive to the ambient air temperature and changes in relative humidity. This record gives insight into local temperature shifts in response to insolation and atmospheric changes over time.

*To be submitted as:* Morrissey, A., Scholz, C.A., and Russell, J.M., TEX<sub>86</sub> paleotemperature proxy application at the world's largest desert lake, Lake Turkana, Kenya to the appropriate journal.

#### **Abstract**

The detailed paleohydrological record of Lake Turkana, the largest lake in the eastern branch of the East African Rift, is necessary for determining the connectivity between adjacent watersheds in tropical Africa. The migration of both the Intertropical Convergence Zone (ITCZ) and the Congo Air Boundary (CAB) constrain rainfall amount and duration for most of East Africa. Lake Turkana, in northern Kenya, is the world's largest desert lake and experiences two ITCZ-associated rainy seasons annually, with cumulative rainfall of ~200 mm/yr. Evidence from new continuous, high-fidelity sediment core records and high-resolution CHIRP seismic reflection data suggests Lake Turkana received enough rainfall during the African Humid Period (AHP) to fill the lake to its sill (100 m above current lake level) and spilled over into the White Nile River system. An atmospheric configuration with an eastward-shifted CAB over the Turkana region and the northern Kenya Rift is invoked as an additional source of rainfall for the catchment. This configuration began abruptly at ~11 ka and lasted until ~5 ka when Lake Turkana became a closed basin and was cut off from the White Nile. Prior to the AHP, Lake Turkana

experienced at least two desiccation events following the Last Glacial Maximum at 18.5 and 17 ka when the lake was at least 100 m lower than modern, as evidenced by basin-wide, high-amplitude reflections and  $^{14}\text{C}$ -dated shallow water facies in sediment cores. Lake level fluctuations generally follow trends in mean solar insolation, however the onset of lake level extremes are much more abrupt than rates of insolation change. Lake Turkana's location in relation to atmospheric convergence and dynamic rainfall patterns makes it susceptible to extreme climate change over relatively short timescales.

## 1 Introduction

Solar insolation change and the Intertropical Convergence Zone (ITCZ) migration are commonly invoked as causes for changes in amount and geographical distribution of rainfall in tropical climate on orbital timescales (Trauth et al., 2001). More abrupt climate shifts may be associated with sea surface temperature (SST) variability and vegetation feedbacks (deMenocal et al., 2000; Camberlin et al., 2001; Castañeda et al., 2009; Verschuren et al., 2009; Tierney et al., 2009, 2011a, 2011b, 2013). These different influences are more or less important depending on the geography and the latitudinal position of a study area (Fig. 1). This study presents multiproxy paleoclimate data from Lake Turkana, the world's largest desert lake and an area that until now contributed only limited information from continuous offshore records on the late Quaternary climate history of tropical Africa. Data presented here constrain high and low lake level extremes associated with changes in the ITCZ and SSTs through time in the Turkana region, and provide insight into African paleoclimate patterns and atmospheric circulation since the Last Glacial Maximum (LGM).

This study extends and refines the record of climate variability and lake level change in the Turkana catchment of tropical East Africa to at least 20 ka. Lake Turkana's extreme desert environment, limited outcrops, and rapid sedimentation rates limited the length and fidelity of late Quaternary paleolimnologic records in past studies (e.g. Butzer et al., 1972; Owen et al., 1982; Halfman and Johnson, 1988; Halfman et al., 1992, 1994; Ricketts and Johnson, 1996; Garcin et al., 2012). The continuous deepwater sediment core and high-resolution seismic records presented here provide a more detailed paleohydrologic record of the Turkana basin that extends further back in time than previous studies (Fig. 2).

The aridity established in parts of East Africa during peak glaciation (Gasse, 2000) continued intermittently through the latest Pleistocene until it slowly gave way to a wetter environment beginning ~12 ka BP. More favorable conditions lasted until the mid-Holocene. This interval when moist conditions prevailed in much of northern hemisphere tropical Africa is commonly referred to as the African Humid Period (AHP) (e.g. Ritchie et al., 1985; deMenocal et al., 2000; Castañeda et al., 2009). This study demonstrates that Lake Turkana experienced more humid conditions and a higher lake level for several thousand years during the AHP, and it provides new constraints on the timing and rates of onset and demise of this climatic optimum.

The watersheds of large lakes commonly span several degrees of latitude, and accordingly, long-term lake level records integrate climate processes across space. Thus, the impact of hydrological connectivity of climate-sensitive lake basins between adjacent watersheds through time is not always taken into consideration in paleoclimate reconstructions. Rainfall throughout East Africa is associated with the migration of enhanced equatorial convection (the ITCZ) that moves several degrees of latitude both north and south of the equator on both seasonal (Fig. 1) and longer timescales. Changes in evaporation associated with vegetation cover and catchment size can exacerbate or inhibit lake level changes during periods of aridity and high humidity (Castañeda et al., 2009; Lyons et al., 2011). Reconstructed water level records from lakes across the region display consequential, sometimes drastic, lake level fluctuations over just a few centuries (Lamb et al., 2007; Garcin et al., 2009; Verschuren et al., 2009; Lyons et al., 2011), leading to opening and closing of adjacent lake systems.

The amount and distribution of water across the African continent controls the dispersal of human populations (Gasse, 2000). Overflow conditions for Lake Turkana provide an additional input into the Nile system (Hopson, 1982; Johnson et al., 1987), which affected the annual flow dynamics of the Nile and likely impacted nascent communities living near the river in the mid- to late-Holocene. The hydrologic closure of Lake Turkana into the Nile River in the mid Holocene reduced Nile flow and likely had negative societal ramifications for groups of people living near the Nile River in Predynastic Egypt (Stanley et al., 2003; Williams et al., 2006; Williams, 2009). The Nile River played a critical role in sustaining human communities of northeast Africa for thousands of years and continues to do so today (Butzer, 1976; Nicoll, 2001; Stanley et al., 2003; Williams, 2009). The loss of Lake Turkana outflow and associated aridification of the Nile region likely promoted the consolidation of groups along the Nile River, which led to land cultivation and planned irrigation.

Here we focus on the paleoclimatological factors that impact lake level change in Lake Turkana by analyzing changes in lithology in sediment cores along with correlative high-resolution seismic sequences that provide a detailed record of deepwater lake deposits that have accumulated since the LGM. The objective of this paper is to present a global climate context for a 20 ka paleoclimate record from Lake Turkana in northern Kenya and describe its role in East African hydrology. This continuous record provides a new perspective on Turkana paleoclimate since the LGM that has not yet been discussed in a context of paleohydrological connectivity and associated changes over time.

## **2 Study area**

Lake Turkana is the largest lake in the Eastern Branch of the East African Rift System at 250 km long, ~30 km wide, and with a maximum depth of ~120 m (Fig. 1). It is situated between 2.3° and 4.6° N latitude in the northern Kenya Rift within a depression between the Kenyan and Ethiopian Highlands. The entire water column is well mixed because the mean lake depth is only ~30 m and the area experiences pervasive unidirectional winds from the north with an average speed of 11 ms<sup>-1</sup> (Lake Turkana Wind Power, 2012), and diurnal winds from the southeast in the South Basin (Hopson, 1982). The lake is slightly saline (2.5 ppt) and mildly alkaline (pH = 9.2)(Yuretich and Cerling, 1983). The Omo River drains the southern part of the Ethiopian highlands (Fig. 1) and provides the lake with 80–90% of its water (Yuretich, 1979; Hopson, 1982; Yuretich and Cerling, 1983). The Kerio and Turkwel Rivers and ephemeral, rainy-season streams provide additional hydrologic inputs.

The sedimentary subbasins of the lake are the result of extension on large half-graben fault systems (Fig. 3) associated with the north-south-striking continental rift (Dunkleman et al., 1988). The lake has three main bathymetric basins, each with volcanic islands near their centers. A broad shield volcano, referred to as “the Barrier” (Brown and Carmichael, 1971; Furman et al., 2004), dams the southernmost margin of the lake. Prior to the eruption of this edifice, Lake Turkana extended farther south into what is now the Suguta Valley (Champion, 1935; Dunkley et al., 1993). The former deep Lake Suguta (Fig. 1) is now the ephemeral Lake Logipi or Suguta Swamp (Garcin et al., 2009; Garcin et al., 2012). Much of the land surrounding the southern part of the lake is covered in intermediate-to-mafic-composition volcanic rocks ranging in age from Miocene to recent;

Teleki's volcano erupted just south of the lake in 1897 (Champion, 1935; Curtis, 1991; Karson and Curtis, 1994).

Past studies characterized sedimentation patterns across the lake as simple basin infill (Yuretich, 1979, 1986; Johnson et al., 1987). Sediment sources to the lake include detrital material from igneous cover and metamorphic basement rocks eroding within the catchment, as well as more limited lacustrine sedimentary rocks deposited during former lake level highstands (Yuretich, 1979, 1986). Authigenic carbonate precipitation is most prevalent in the South Basin, where the influence from the Omo River detrital sediment load is reduced (Yuretich, 1979, 1986; Halfman et al., 1989). Eolian sediment is transported by strong winds, especially in the South Basin. Biogenic material accumulates on the lake floor in the form of amorphous organic matter, diatoms, gastropods, and ostracodes (Hopson, 1982; Halfman et al., 1992). Stromatolites, other microbialites, and carbonate grainstones are present in outcrop adjacent to the southeastern shoreline of the South Basin (Abell et al., 1982; Owen et al., 1982; Hargrave et al., in press).

The lake is hydrologically closed, with the spill point 100 m above the modern lake surface (Garcin et al., 2012). Overfilling of the basin occurred as recently as ~4 ka BP (Halfman et al., 1992; Garcin et al., 2012). At highstand, Lake Turkana's watershed increased the Nile's drainage area by 162,000 km<sup>2</sup> (Fig. 1)(Garcin et al., 2009) by including the southern Ethiopian Highlands and part of the Kenyan Highlands in its catchment. The Nile River watershed presently drains most of northeast Africa north of ~4.5° N and east of ~25° E. Bodies of water within the watershed include Lakes Albert, Victoria, and Edward, which provide most of the river's baseflow due to high year-round rainfall near the equator (Fig. 1). The northern Ethiopian Highlands drain south into Lake Tana and north into the

Atbara River, both of which source the Blue Nile (Lamb et al., 2007; Williams, 2009; Blanchet et al., 2013) and support high flow of the Nile during rainy seasons.

This study focuses on data collected in the southernmost basin of Lake Turkana. The South Basin is an asymmetric half-graben with the main border fault zone on the western side of the basin (Fig. 3). The basement along the border fault is displaced over 1 km, creating a steep lake margin (slopes  $>35^\circ$ ) adjacent to hills and mountains of the western footwall, which are composed of Precambrian gneissic and schistic basement rock (Ochieng and Kagasi 1988; Dunklema et al., 1988). The eastern, flexural margin of the basin exhibits a low-relief ramp margin (slopes  $<5^\circ$ ).

### **3 Materials and methods**

#### *3.1 Seismic methods*

Over 1100 km of high-resolution Compressed High Intensity Radar Pulse (CHIRP) 2D seismic reflection data were collected in the South Basin using an EdgeTech 3100P acquisition system with Discover 3100 v 5.23 software. Seismic lines were acquired in an orthogonal grid with a  $\sim 2$  km line spacing (Fig. 1). CHIRP data were acquired using a swept bandwidth of 4–24 kHz with a dominant frequency near 8 kHz and a sample rate of 0.023 s. The high frequency source yields data with centimeter-scale resolution. The ping rate of the system varies with water depth, but shot spacing is nominally 1 m with a record length of 125 ms. Typical subbottom penetration was  $\sim 35$  m. A Trimble AgGPS 132 receiver was used to acquire navigation data at a sample rate of once per second. The seismic data were conditioned and processed using ProMAX 2D processing software, and fault and seismic stratigraphic interpretations were carried out using Landmark SeisWorks 2D software.

Additional seismic lines were acquired to extend imaging deeper into the subsurface. A 1 in<sup>3</sup> Bolt 600b airgun was used to acquire approximately 140 km of single-channel airgun seismic reflection data along lines that were coincident with CHIRP profiles (Fig. 1). A GeoAcoustics Geopulse receiver and a Chesapeake Technologies Incorporated SonarWiz 4 acquisition system were used for data collection. The depth of penetration of the airgun data is ~70 m, and data resolution is ~1 m.

### *3.2 Sediment core acquisition*

The paleolimnology of Lake Turkana was reconstructed using data derived from three sediment cores (Figs. 1 and 4). Three cores were collected using a Kullenberg piston coring system. Piston cores, 4P, 14P, and 46P are 9.7, 8.5, and 10.6 m in length, and were recovered from 52, 58, and 56 m water depth, respectively. Both 46P and 4P were collected from the northeastern part of the south basin approximately 6 and 8 km from the current shoreline and 4 km apart (Fig. 1). Core 14P was collected ~28 km to the south of 4P and 4 km west of the current shoreline. During the collection of these cores, the Kullenberg system over penetrated the sediment-water interface; accordingly the piston cores do not preserve the youngest part of the sediment record. This was confirmed by mud on the weight stand after the cores were recovered from the water.

#### *3.2.1 Physical properties and core descriptions*

Non-invasive measurements of bulk density and magnetic susceptibility on whole cores were made at Brown University using a GEOTEK MSCL-S whole core scanner. Saturated bulk density from the Gamma Ray Attenuation Porosity Evaluator (GRAPE) and

magnetic susceptibility were recorded at a 1-cm interval. The lithologies of the cores were described immediately after splitting to avoid effects of oxidation and color fading (Figs. 2, 4, and 5).

### *3.2.2 Sediment Core Geochemistry*

The cores were split and subsampled at 8-centimeter intervals. Discrete dry sediment samples were analyzed at Syracuse University for percent total organic carbon (TOC) content by elemental analysis using a COSTECH Elemental Analyzer. The total inorganic carbon (TIC) content was measured by coulometry using a UIC acidifier coupled with a Coulemetrics CO<sub>2</sub> coulometer (Fig. 2).

Scanning X-ray fluorescence for major element chemical analysis was carried out on archive-core halves using a molybdenum-sourced ITRAX scanner. Measurements were taken at a 0.5-centimeter interval at the Large Lakes Observatory at the University of Minnesota–Duluth (Fig. 2). Data was filtered to remove measurements with a mean standard error over 1.5% due to irregularities in core surface profile.

### *3.2.3 Geochronology Methods*

Twenty-four AMS <sup>14</sup>C samples of bulk organic matter, bulk carbonate, plant material, or shells were dated to constrain the chronology of the three piston cores (Fig. 6 and Table 1). The flexible Bayesian age-depth program, “Bacon,” (Blaauw and Christen, 2011) was used to construct the age models of all three cores. Within this model, the ages were calibrated using the IntCal09 calibration curve.

## 4 Results

### *4.1 Basin framework and late Quaternary sediment distribution*

High-resolution seismic data show many intrabasinal normal faults across South Basin (Fig. 3) with offsets between 1 and ~8 m on shallow depositional surfaces and on the lake floor. Intrabasinal faults are both synthetic and antithetic to the east-dipping main basin border fault on the western side of the lake. Sediment accumulation patterns indicate growth faulting, with sediment accumulation rates much higher in the open basin and near the border fault compared to the eastern, flexural margin (Figs. 3 and 4). Conformable sedimentary sequences thicken to the west along the border fault. Sediment packages thin considerably and onlap in shallower water (~40 m) along the flexural margin. Many sediment packages along this margin are truncated due to erosion or non-deposition during low lake levels (Fig. 4). A sediment bypass zone exists along an area within 2–3 km of the eastern shore (Fig. 4). In much of this zone, sediment at the sediment-water interface is 5 ka in age or possibly older (geochronology and sequence boundaries discussed in results). Fine-grained sediments only accumulate more than 3 km to the west of the eastern shore, in water depths of ~55 m or more (Fig. 3).

### *4.2 Seismic stratigraphy and lithologic correlation*

#### *4.2.1 Seismic Sequences*

The extensive CHIRP seismic data set helps to laterally extend events interpreted from sediment cores across the basin using subsurface stratal geometries. Significant seismic reflections (stratigraphic surfaces) were picked throughout the South Basin

dataset. Letters denote sequence names, and letters advance towards the recent. Sequences outlined below can be seen in Fig. 4 and Table 2.

Sequence A: T9, a high amplitude reflection, is the lower boundary for Sequence A and the lowermost widespread horizon in the CHIRP dataset, and serves as acoustic basement for the late Quaternary record (Fig. 4 and Table 2). T9 is observed on profiles on the eastern side of South Island and is absent in many of the seismic lines in the western part of the basin. The upper boundary of Sequence A is horizon T10, a high-amplitude, laterally continuous reflection present in most seismic lines. Sequence A onlaps along the eastern margin onto an older, high-amplitude reflection. Sequence A between T9 and T10 is characterized by a low-amplitude, nearly transparent package. T10 is relatively shallow on the flexural margin where the sedimentary sequences are condensed and onlap older coarse-grained shoreline deposits (Figs. 3 and 4). Sequence A was not sampled by any of the sediment cores.

Sequence B: Just above T10, a package of low amplitude reflections is present. This sequence lacks internal structure and is thin (< 250 cm) near the eastern shore but expands dramatically in a westerly direction, to a maximum of ~10 m. This package is truncated above by another high amplitude reflection, T11, that also onlaps older, nearshore deposits (Fig. 4). Sequence B was sampled in piston cores, which are described in a subsequent section.

Sequence C: The sequence above T11 is characterized by transparent, low-amplitude reflections that transition upward into higher amplitude, flat-lying reflections. A marker horizon, T11\_1a, delineates this transition. This upper part of this sequence displays a reduced amplitude towards T11\_1. Surface T11\_1 is a subsequence boundary

based on a distinct change in spatial sediment depositional patterns. It is observed between Sequence C and the overlying sequence where sediment shifts from basin-wide deposition to focused deposition in deep water.

Sequence D: The seismic character of Sequence D displays a distinct amplitude and frequency character compared to underlying sequences. This uppermost sequence between T11\_1 and T\_12 is characterized by low amplitude, low frequency flat-lying reflections. An unconformity is observed within this sequence on several nearshore seismic lines (Fig. 7) and is marked by horizon T11\_2. Surface T12 is the uppermost horizon picked and is observed near the top of core 4P, which is described below.

#### *4.2.2 Additional seismic features*

In the subsurface data, several progradational packages and distinct changes in slope of lakefloor and subsurface horizons are interpreted as paleodeltas (Fig. 8) or terraces. These features are paleoshoreline indicators that have been buried in the subsurface to depths of several meters. Two sets of these features are seen at two different subsurface depths. The sound source of the CHIRP data is not powerful enough to penetrate into these features, however, the airgun data penetrates into these deposits, and basinward prograding clinoforms are readily observed (Fig. 8). The exact time of formation is not available, but they are associated with lowstands of Lake Turkana before the onset of the AHP and probably developed between 17 and 15 ka.

#### *4.3 Geochronology*

The 24 AMS  $^{14}\text{C}$  samples from the three cores (Fig. 6 and Table 1) range in age from 19,700 to 860 yr BP. Core 46P is the oldest recovered record and is dated from 19,700 to 5,870 yr BP constrained by 13 AMS  $^{14}\text{C}$  dates. Core 14P is 13,480 yr BP at the base and 380 yr BP at the top, based on 6 AMS  $^{14}\text{C}$  dates from organic-rich mud. Core 4P is constrained by 4 AMS  $^{14}\text{C}$  dates, and has ages of 860 yr BP at the top and 3,730 yr BP at the base.

Radiocarbon dates are not corrected for a reservoir effect. The new radiocarbon data reveal similar results for the different materials dated including macrophytes, bulk organic matter or bulk inorganic carbon (Table 1, Fig. 6). We acknowledge that Junginger et al. (2014) established a reservoir effect for Lake Suguta, adjacent to Lake Turkana, however this approach is consistent with other  $^{14}\text{C}$  studies from Lake Turkana (e.g. Owen et al., 1982; Halfman and Johnson, 1988; Berke et al., 2012b; Garcin et al., 2012), which do not normalize for reservoir effect in their age models, as old carbon sources in the catchment are relatively minor. Using a radiocarbon date from a living snail, Garcin et al. (2012) determined that the present-day reservoir effect is negligible ( $\sim 10$  yr).

#### *4.4 Core lithostratigraphy, geochemistry, and correlation*

The three sediment cores, 46P, 14P, and 4P were correlated using multiple proxies in order to generate a composite paleolimnological record from 20 ka BP to present. Cores 46P and 4P comprise most of the composite record, however a  $\sim 1.2$  kyr time gap exists between the two cores, and core 14P is used to bridge the time gap, as it overlaps the top of 46P and the base of 4P (Figs. 4 and 5). Both organic and inorganic carbon, XRF-derived Ca counts, magnetic susceptibility, and radiocarbon ages were used for correlation between the three cores used in this study (Fig. 5). The composite record is separated into

sedimentary units. The core lithologies, geochemistry, and geophysical properties are described starting from the bottom of the composite record (Fig. 2).

Unit 1 (19–14 ka): The base of the unit is the oldest sediment analyzed; it is composed of carbonate-rich, green mud interspersed with black sand grains and diatoms and sand lenses spaced 15–20 cm apart (Fig. 2). TIC content ranges from ~0 to ~7% with an average of  $1.1 \pm 1\%$ , while the TOC ranges from ~1 to ~6%.

Unit 2 (14–11 ka): Sediment is light brown-green mud and lacks laminations or clear bedding. TOC increases up section from ~1 to ~3% and TIC is high but variable with values of 2–4 % (Fig. 2).

Unit 3 (11–4.5 ka): This unit is made up of dark green-gray diatomaceous mud with rare light green laminations that are 3–5 mm thick and occur every 10–15 cm (Fig. 2). TOC values up to 6% are observed with abundant diatoms and extremely low values of TIC (0.3% or less). There is no evidence for bioturbation and little lithologic variation within this unit.

Unit 4 (4.5 – 0.7 ka): This unit is composed of diatomaceous green-brown mud with fine sand intervals with some bedding present (Fig. 2). TIC values for this unit have an average value of  $1.9 \pm 0.4\%$ , whereas total organic carbon has an average of  $1.1 \pm 0.3\%$ . TIC and TOC covary within this unit. Scanning XRF elemental analyses show that downcore Ca counts closely track the changes in percent TIC. There are no extremely high or low excursions in any of the proxies measured in this interval. The record is continuous, with no obvious unconformities present in the core or in the nearby seismic sections. Near the middle of this unit there are more occurrences of light tan-brown laminations that are spaced 2–10 cm apart, with rare occurrences of denser, light tan-brown 2–3 cm thick beds.

The upper 300 cm of this unit contains is darker grey-brown mud interbedded with the green-brown mud with decreasing diatoms. The uppermost 0.40 m is green-tan mud with abundant diatoms and rare amorphous organic matter. There are interbeds and laminations of lighter tan mud that are 0.5–2 cm in thickness and 3–5 cm apart, and lighter yellow-tan clay laminations that are 0.3 to 0.5 cm thick and ~10 cm apart and more diatom-rich.

The lithology record has been correlated to the seismic data using variations in density and lithology compared to seismic reflection amplitude and seismic sequence character. Radiocarbon dates from cores provide age constraints for limnological changes interpreted from seismic data (Fig. 6; Table 1). The base of Unit 1 correlates to horizon T10 in seismic reflection data; radiocarbon ages from the lowermost sediment of Unit 1 indicate the T10 horizon is approximately 19 ka in age. T11 correlates with sediment that is dated to be ~17.8 ka. T11\_1 correlates to sediment in Unit 4 that is dated at ~4.3 ka. T11\_2 has an age of approximately 2.3 ka, based on radiocarbon dates from Unit 5.

## **5 Discussion**

### *5.1 Lake level indicators from sediment cores and seismic reflection data*

Sediment physical properties, geochemical analyses, and observations of stratal terminations and subsurface features were interpreted to produce a lake level record for Lake Turkana (Figs. 2 and 4). Several unconformable surfaces and onlapping sequences (Table 1) are observed in seismic data, and are correlated to changes in core lithology and geochemistry, suggesting regressions and transgressions over the last 20 ka. This record provides insight on local paleohydrological change as well as regional climate processes.

At the base of the composite sediment record (Fig. 2), high TIC (~6%), high calcium counts (near 100,000 counts), high bulk density (~1.6 g cm<sup>-3</sup>), and the presence of sand suggest that Lake Turkana was smaller in volume and in surface area. Reduced lake volume concentrated dissolved ions, increased authigenic calcite precipitation, and induced the basinward migration of littoral facies. The high-amplitude reflection (T10) that correlates to this sediment interval is widespread throughout the lake, indicating this lowstand event affected the depositional patterns and geochemistry of deep parts of the lake, and was not isolated to nearshore environments. The deepest region where this reflection retains its high-amplitude character is 130 m below current lake level (230 masl). This is interpreted as a lowstand of at least ~110 m below current lake level that extended from ~19 until 18 ka. The South Basin was likely desiccated during this interval. Paleodeltas observed in seismic data are probably associated with this regression as they are coeval with T10, however the sequence of deposition cannot be constrained due to ambiguities within the seismic data. The younger AHP sequences onlap all of these features, indicating the progradational features must all be substantially older than ~12 ka.

Following this lowstand, lake level rose for a short period of time as indicated by an increase in organic carbon, a decrease in saturated bulk density and seismic amplitude as well as an absence of sand in the interval (Fig. 2). The amount of the lake level rise is not precisely constrained, but the core site was likely in several meters of water, and perhaps as high as the modern lake (~360 masl) as indicated by similarities in geochemical measurements to modern samples. This increase in lake level persisted from ~18 until ~17.5 ka which was followed by another lowstand at ~17 ka (Fig. 2), as indicated by an increase in density from the presence of mafic lithic sand grains and an increase in calcite

preservation. This interval correlates to another high amplitude reflection (T11) in the seismic data indicating a lowstand (Figs. 2 and 4). The deepest part of the basin showing this seismic character is ~120 m (240 masl) below the current lake level, which indicates the South Basin was probably desiccated during this interval (~240 masl).

From ~17–13 ka, brown-green mud and clay dominate the lithology. The TIC and TOC values are relatively low in this interval with TIC increasing around 14 ka. This suggests lake level remained low but the lake was not desiccated during this interval, with a possible subsequent decrease between 15 and 14 ka. Above this interval, organic and inorganic carbon, saturated bulk density, seismic character, and sediment type change. The abrupt and substantial increase in organic carbon to nearly 6% and decrease of TIC to 0% suggest that a deep-water environment was established quickly and persisted for several thousand years (Fig. 2). During this period of extremely low inorganic carbon preservation, water column stratification probably developed, resulting in anoxic bottom waters with low pH inhibiting calcite deposition. The seismic data in this interval are characterized by continuous and flat-lying reflections, indicative of an undisturbed, deep-water environment. The sediment is finely laminated with no evidence of bioturbation throughout the interval, indicating bottom water anoxia. These conditions likely persisted from ~12.5 until ~5.0 ka (Fig. 10). The consistent nature of the sediment record indicates high, stable lake level during this period, a deep lake, and a hydrologically open system. At overflow, lake level reached ~460 masl, which is 100 m higher than today. During this time period the lake overflowed into the Nile River via the Turkana-Nile River (Garcin et al., 2012)(Figs. 1 and 4). Changes in TOC over this interval may represent decadal-scale drops in lake level, dilution by allochthonous material, or both (Fig. 2).

After 5 ka, the pH of deep water increased as indicated by an abrupt increase in TIC. From 5 ka to ~4 ka, inorganic carbon increased and organic carbon decreased over a few hundred years, accompanied by an increase in sediment bioturbation, indicating a regression to lake levels comparable to that of the modern lake. It was during this interval of time that the lake became hydrologically closed and no longer contributed outflow to the White Nile drainage.

The seismic reflection data display a significant angular unconformity dated at ~2.3 ka by correlation to the cores (Fig. 7). In deep water (>55 m), sediment layers are conformable and no evidence of lowstand conditions is observed. The limited spatial extent of this unconformity suggests there was moderate lowstand (~40 m below modern lake level) during the late Holocene. This lowstand is corroborated by radiocarbon-dated shorelines that indicate a regression beginning at ~5.2 ka (Garcin et al., 2012). Following this lowstand, lake level once again increased to near modern levels as indicated by burial of the lowstand unconformity. TOC and TIC values remain relatively constant to the top of the sediment record (Fig. 2) and no additional truncations are identified in seismic data. Archaeological sites dated to ~1000 yr BP thought to have been located lakeside indicate lake level may have been ~20 m (~380 masl) higher than today (Owen et al., 1982). This suggests moderate a lake level rise in the latest Holocene before it returned to its current level (~360 masl)(Fig. 2).

## *5.2 Lake Turkana's connection with the Nile River*

The spill point of Lake Turkana drainage is ~90 km northwest of the present-day lakeshore, where it connects to the watershed of the White Nile via the relict Turkana-Nile

River (Fig. 1). The Nile River has been the primary water source for inhabitants of the desert of Egypt and Sudan since prehistoric times (Nicoll, 2001; Stanley et al., 2003; Williams et al., 2006; Williams, 2009). Nile River historical flow records have shown significant fluctuations in the past; the influence of flow changes on contemporaneous civilizations is well documented (Stanley et al., 2003; Williams et al., 2006; Williams, 2009). Nicoll (2001) describes a decline in occupancy in the northern Nile region probably related to a changing environment and increase in aridity starting around 6 ka and near abandonment by 4.2 ka based on the frequency of hearths occurring in the archeological record. Lake Turkana's transition from a hydrologically open to a closed basin just after ~5 ka was significant for the sustainability of the base flow of the Nile River. Evidence showing a slow decline in plant and animal diversity in the Nile region (Said, 1993; Stanley et al., 2003) is correlative with a change from deep, possibly stratified water in Lake Turkana to a closed, evaporative lake system (Fig. 2). It is during this time (~6–4 ka) when fine-grained, organic rich sediments (up to 6% TOC) slowly transitioned to slightly coarser grained material with less organic matter and higher percentages of carbonate (1–3% TIC). This transition marks the last contribution of Lake Turkana to the White Nile River.

### *5.3 Regional lake level comparison*

Extreme variations in lake level are characteristic of many lakes in East Africa in the late Quaternary. A complex, interconnected system of lake outflows and rivers from the Western Branch of the East African Rift sustain the base flow White Nile River today (Fig. 1)(Blanchet et al., 2013). In the past, Eastern Branch lakes played a more significant role in providing water for the Nile River System. During a time of regional lake highstands, such

as the AHP (~12–~5 ka), an open hydrological system was established across the northern Kenyan Rift Valley.

Lake Victoria (Figs. 9 and 1) is one of the modern sources for the White Nile, overflowing into Lake Albert via the Victoria Nile and Lake Kyoga. Lake Victoria was desiccated during the LGM and transgressed through the late Pleistocene (Johnson et al., 1996; Stager and Johnson, 2000; Beuning et al., 1997a). Lake level was high during the AHP, but diatom studies show that Lake Victoria levels likely dropped during the period when lake level in Lake Turkana was rising, 12–10 ka, (Stager and Johnson, 2000) and oxygen isotope values from lake-sediment cellulose in Victoria greater than 5‰ indicate closed basin values from 13–10 ka (Beuning et al., 1997a). The compound-specific hydrogen isotope proxy data derived from leaf waxes ( $\delta D_{\text{wax}}$ ) in sediment cores can be used as a proxy for past precipitation accumulation due to the enrichment of deuterium in raindrops via the “amount effect” (Dansgaard, 1964; Rozanski et al., 1993). A compound-specific  $\delta D$  record generated from a Lake Victoria core suggests that Early Holocene Lake Victoria lake levels increased between 10–9 ka due to increased rainfall in the region (Berke et al., 2012a). Strontium isotope ratios of shell and fish remains from the White Nile were used as tracers for the Victoria contribution to the Nile, and indicate that Victoria supplied water to the Nile by 11.5 ka but this flow was probably subsequently disrupted at times during the Holocene (Talbot et al., 2000) and possibly as early as 15 ka (Williams et al., 2006). Neither of those studies, however, address the mid Holocene Victoria lake record in detail. Values of the  $\delta D$  record are less than -110‰ at this time, or D-enriched, suggesting that the amount of rainfall accumulating at this time was probably higher (Berke et al., 2012a), but then slowly decreased to a closed system by around 7.3 ka (Stager

and Johnson, 2000; Beuning et al., 1997a). The oxygen isotope values of cellulose isolated from lake sediment cores, a proxy for the evaporative properties of lake water, decreased after 5.4 ka to modern values of  $\sim 4\text{‰}$ , indicating higher Lake Victoria levels since the mid Holocene (Beuning et al., 1997a). Importantly, the balance of evidence suggests that Lake Victoria was an intermittent contributor to the White Nile during much of the AHP, a time when Lake Turkana's level was high and contributing significant volumes of water to the Nile.

Lake Albert (Fig. 4) has two main inputs, the Semliki River draining Lake Edward and the Victoria Nile. Lake Albert discharges to the north, providing 83% of the base flow for the White Nile River (Hurst, 1957). Late Quaternary palynological records from Lake Albert (Fig. 9) suggest dry periods from 18 to 12.5 ka, 11.4 to 10.9 ka and 10.4 to 9.9 ka, but no data exists for much of the early Holocene from Lake Albert (Beuning et al., 1997b). The loss of Lake Albert discharge to the Nile system was detrimental to perennial flow, suggesting that another source was required to sustain the Nile River through the mid-Holocene. Lake Turkana overflowed during the time period that spans all of the dry periods in Lake Albert, and was probably the alternative source of base flow of the White Nile.

Lake Tana is located in the Ethiopian Highlands on the northern side of the drainage divide at an elevation of 1790 m, and is the source of the Blue Nile. It has a complex paleohydrology (Lamb et al., 2007; Marshall et al., 2011) with a history of fluctuations comparable to Lake Turkana (Fig. 9). Since Lake Tana and Lake Turkana share drainages of geographic proximity, and their catchment precipitation is strongly dependent on the passing of the ITCZ, it is unsurprising that they exhibit similar lake level histories. Lake Tana experienced dry intervals from  $\sim 18.7$  ka to  $\sim 15$  ka, just before 12 ka and near 8.5 ka

(Lamb et al., 2007). Blanchet et al. (2013) suggest the Blue Nile was less of a contributor to the Nile River after 8.5 ka and that the White Nile supported the main Nile River flow until ~4 ka. No evidence at 4.2 ka for a lowstand event is observed in Lake Tana records, suggesting that a source other than the Blue Nile was responsible for the failure of White Nile flow at the end of the AHP. The new Lake Turkana records suggest that reduced input from Turkana and its upstream tributaries in the mid Holocene were responsible for the failure of the Nile River, which was coincident with societal collapse in Ancient Egypt. Elimination of the annual flood season in the Nile Valley led to migrations out of nascent riparian communities in effort to find alternate water sources (Stanley et al., 2003).

The Omo River discharge off the southern Ethiopian Highlands was likely only one major input to Lake Turkana during the African Humid Period. The Suguta Valley (Figs. 1 and 9), located just to the south of Lake Turkana, is presently the main terminal basin for drainages discharging off the northernmost part of the Kenyan highlands. Today these drainages enter the Suguta Valley and form an ephemeral playa lake (Garcin et al., 2009). When Paleo-Lake Suguta was last at its highstand in the early Holocene, it spilled over into the Lake Turkana watershed and provided an additional hydrological input from the Kenyan Highlands (Garcin et al., 2012; Junginger et al., 2014). The last highstand of Paleo-Lake Suguta was 5–6.5 ka (Junginger et al., 2014), and evidence suggests that Lakes Bogoria and Baringo (Fig. 1) also spilled over into Suguta Valley around 10.5 ka (Young and Renaut, 1979; Renaut and Owen, 1980; Garcin, 2009). The duration of the Baringo-Bogoria highstand event is not known, but this highstand system would have produced an open hydrologic system throughout the northern Kenyan Rift Valley that provided additional input for the Turkana-Nile River.

Additional ancient tributary inputs of the Nile River that cannot be overlooked include ancient fluvial and lacustrine environments in the Eastern Sahara. Pachur and Kröpelin (1987) described the Wadi Howar (17-18°N, 27-31°E) as a large flooded valley with small lakes and streams that flowed eastward out of western Sudan into the White Nile at least intermittently between 9.5 and 4.5 ka. Sediments from the catchment include both lacustrine and fluvial deposits with channels incised into lacustrine clays, suggesting significant water level fluctuation over the first half of the Holocene (Pachur and Kröpelin, 1987). We postulate that this tributary along with Lake Turkana and its upstream inputs into the Turkana-Nile provided additional flow to the White Nile during the AHP. Both ultimately waned at or shortly before the downfall of the Old Kingdom of Egypt at 4.2 ka.

#### *5.4 Climatic implications*

It is widely documented that much of northern and eastern Africa was more humid from approximately 12 to 6 ka (Ritchie et al., 1985; deMenocal et al., 2000; Castañeda et al., 2009; Garcin et al., 2012; Junginger and Trauth, 2013) due to changes in insolation-driven climate processes, and the new lithological and geochemical data from Lake Turkana are broadly consistent with those observations. Turkana's ancient upstream inputs, Lake Bogoria, Lake Baringo, and Paleolake Suguta also overflowed during different intervals of the AHP (Young and Renaut, 1979; Garcin et al., 2009). From these records of the Eastern Branch rift valley lakes, it is clear that the durations of lake highstands increase toward the north. Lake Bogoria and Baringo were last at highstand around 10.5 ka (Young and Renaut, 1979) and Lake Suguta was open with Lake Turkana until at least 8.2 ka (Garcin et al., 2009) and probably until 5-6.5 ka (Junginger et al., 2014). Lake Turkana was open through

the mid Holocene. Even farther to the north, Lake Abhe (11.18°N, 41.80°E; Fig. 9) remained high until around 4 ka (Gasse et al., 1977).

The large-scale climate implications derived from these records are complex due to the nature of African climate. Today Lake Turkana experiences two monsoonal rainy seasons from the twice-a-year passing of the ITCZ, but with minimal annual cumulative rainfall over the lake surface (<200 mm/yr) and high rates of evaporation (>1500 mm/yr)(Yuretich and Cerling, 1983). The ITCZ tends to follow the areas of peak insolation, thus slightly changing the pathway of high rainfall migration over long timescales. Greater annual inter-hemispheric variation in solar insolation occurred during the AHP that increased precipitation at northern tropical latitudes in Africa (Verschuren et al., 2009). During the AHP, the ITCZ annual migration path was shifted northward, residing north of the equator for more of the year, providing more rainfall for the northern Kenya Rift region. Whereas the specific location of high rainfall over the watershed is uncertain, it is evident that the annual hydrologic input to the lake was greater during the AHP, resulting in overfilling of Lake Turkana.

An additional supplier for moisture to East Africa is the air mass associated with the Congo Basin, which derives its moisture from the Atlantic Ocean, and the boundary between easterly-derived Indian Ocean air and westerly-derived Atlantic Ocean air is known as the Congo Air Boundary (CAB)(Nicholson) Today it is rare when moisture from the CAB travels as far east as the Lake Turkana region (Junginger and Trauth, 2013). Additionally, the easternmost parts of East Africa are at least partially isolated from Congo Basin moisture, due to the high topographic relief of the Rift Valley separating moisture zones across East Africa (Tierney et al., 2011b; Berke et al., 2012a). Lake Turkana lies in a

regional depression without the orographic constraint of a large footwall uplift near the confluence of the ITCZ and the easterly shifted CAB. Enhanced pressure gradients over the western Indian Ocean forced the CAB eastward during the AHP, allowing for more annual rainfall to accumulate in the Turkana and Suguta regions (Junginger and Trauth, 2013). The unique positioning along this boundary provided the Turkana area with two different moisture sources during the AHP.

Due to its proximity to the coast, the Eastern Branch of the rift valley is more sensitive to the behavior of the Indian Ocean monsoons, Indian Ocean SST variability, and advection of moisture from the ocean onto the land surface. The reduction in lake surface elevations northward along the Eastern Branch of the rift valley suggests a coupled reduction in advection of Indian-ocean moisture along the coast through the mid Holocene. Lake Challa, a crater lake on the southeastern flank of Mt. Kilimanjaro, is reliant upon Indian Ocean for moisture. Hydrogen isotope ( $\delta D_{\text{wax}}$ ) records from Lake Challa show a decrease in moisture availability as the AHP progressed, supporting a disturbance in Indian Ocean monsoon dynamics during the African Humid Period (Tierney et al., 2011b). Lake Abhe, in the horn of Africa, shows high lake levels longer than most other records (Gasse et al., 1977), also supporting a northward shift of increased rainfall. A recent study by Tierney et al., (2013) suggests that Indian Ocean SSTs have a strong control on rainfall amount along the eastern coast of Africa.

Increased insolation during the AHP and associated land surface temperature increase would have led to greater advection of moisture onto the continent from both the Atlantic and Indian Oceans, and extended the monsoonal rainy seasons. With an increase in annual convergence in the northern tropics, the Turkana region received more annual

cumulative rainfall over not just the Ethiopian highlands, but likely over the lake surface. In addition to the enhanced ITCZ and possibly additional CAB influence, increased vegetation coverage during more humid intervals increases moisture recycling and can lead to higher cumulative rainfall in a region (deMenocal et al., 2000). Climate feedbacks such as increased cloud cover coupled with vegetation feedbacks would also have reduced the opportunity for evaporation (Kutzbach and Street-Perrott, 1985; Lenters et al., 2005). This is evident in the lake record from Turkana. High values of organic carbon and deepwater facies suggesting water column stratification, requiring a deeper, more stable lake.

The lake level record from Lake Turkana indicates significant fluctuations in rainfall since the LGM. Widespread, laterally continuous seismic sequences and organic-rich sediment (Fig. 4) intervals from this study indicate that during the AHP, Lake Turkana was a deep lake that was likely stratified. The increased rainfall that facilitated a deep lake and vegetated landscape was probably affected by the intensification of Indian Ocean Monsoons and is also consistent with an incursion of Atlantic-derived moisture from the eastward movement of the CAB. Through the mid Holocene, the locus of precipitation progressed northward, and was likely due to a shift in warm SSTs to the northern Indian Ocean. This is manifested in lower lake levels in East African Lakes Challa and Turkana, but for highstands in more northerly lakes such as Abhe (Tierney et al., 2011b, 2013; Gasse et al., 1977). In Lake Turkana this is evident from seismic character that is less laterally extensive, lower frequency subsequences that onlap further basinward than AHP sequences (Fig. 4).

## **6 Conclusions**

- The water level in Lake Turkana fluctuated by approximately 200 m since the Last Glacial Maximum. Evidence from sediment and facies type, geochemical analyses, geophysical measurements, and paleoecological indicators indicate that lake level has fluctuated significantly over the past 20 ka in the Turkana Basin, from extreme lowstands and likely desiccation during the LGM to highstand conditions during the AHP.
- There is evidence at 18.5 ka and 17 ka for lake levels more than 100 m below current lake level, and evidence at ~14 ka and 2.3 ka for lake levels 10's of meters lower than today.
- Stable, high lake levels and an open system with the Nile River occurred abruptly beginning at ~12.5 ka and lasting until ~5 ka.
- During the AHP, Lake Turkana, along with upstream watersheds, spilled over into the watershed of the Nile River, providing a significant water source that sustained White Nile flow.
- The dramatic changes in Turkana lake levels presented here are consistent with shifts in the migration path of the ITCZ and intensification of African Monsoons during the AHP. Data presented here cannot characterize source of precipitation in the Turkana catchment, but the timing and amount of rainfall is consistent with influence of Congo-derived moisture (CAB migration) during the AHP.
- Lake level fluctuations approximate trends in mean solar insolation, however the onset of lake level extremes are much more abrupt than rates of insolation change.
- Sediment and seismic records presented here suggest that the hydrological closure of Lake Turkana and disconnection to the White Nile watershed at ~5 ka is

contemporaneous with documented Nile low flow and the decrease in diversity of plants and animals from Predynastic Egypt (~6 ka) through the time of the fall of the Old Kingdom (~4200 ka).

## **7 Acknowledgements**

We thank the government of Kenya for research permissions. Financial support was provided by the sponsors of the Syracuse University Lacustrine Rift Basins Research Program. We thank the National Oil Corporation of Kenya for assistance during field operations. The authors thank the people of Loiyangalani and the Turkana Rift Valley, for their cooperation, assistance, and hospitality during multiple field seasons at Lake Turkana. We would also like to acknowledge the collaborators and research staff at Syracuse University as well as Dr. James Russell at Brown University, Dr. Erik Brown and Aaron Lingwall at the Large Lakes Observatory at the University of Minnesota-Duluth, and the Lacustrine Core Repository (LacCore) at the University of Minnesota-Twin Cities where sample processing was carried out. Support for radiocarbon dating was provided by the U.S. National Science Foundation. Dr. Maarten Blaauw provided considerable assistance in generating the age model. Seismic data analysis was completed using software provided on a grant from Landmark Graphics Corporation. Reviews from Editor Finn Surlyk and two anonymous reviewers helped greatly improve the original version of this manuscript.

## 9 Figures

**Fig. 1. (A)** Topography of Lake Turkana and its watershed with black box indicating study area. Lake Turkana Highstand Watershed delineated (fuchsia). Blue polygon with black outline defines current Lake Turkana shoreline. Palest blue polygon indicates highstand shoreline of Lake Turkana. Brown line indicates current drainage divide between Suguta Valley and Lake Turkana. Black dashed line delineates paleo-river connecting Lake Turkana to the White Nile. Black arrow indicates location of outflow location of Lake Turkana during highstand. Other geographic locations added for reference. **(B)** Data map of South Basin of Lake Turkana. Gray solid lines are CHIRP seismic tracklines, featured profiles traced in black. Thin, dot-dashed black lines indicate Airgun seismic tracklines. Bold dashed line is MCS trackline. Red dots are piston core locations. **(C)** Black box outlines location of Lake Turkana on the African continent

and bold dashed lines denote northern- and southernmost extent of the annual migration of the ITCZ and thin, solid lines denote the location of the CAB at its extremes. Nile River watershed is (including highstand Lake Turkana) in grey, and blue lines are major rivers.

**Fig. 2.** Summary of data used for interpretation of lake level through time. The 3 different cores from which the data are derived are plotted in blue (4P), purple, (14P), and red (46P). Vertical axis is time in Cal. Yr BP. **(a)** Organic carbon is plotted in weight percent, and was sampled in each core at an 8-cm interval. Black triangles are sample locations for radiocarbon dating. **(b)** Inorganic carbon is plotted in weight percent, and was sampled in core at an 8-cm interval. **(c)** Gamma Ray Attenuated Porosity Evaluation measures saturated bulk density in  $\text{g/cc}^3$ . **(d)** Magnetic susceptibility and **(e)** calcium are both reported as counts per second, whereas calcium is divided by 1000 for simplification. **(f)** Bold black lines with labels denote significant horizons from high-resolution CHIRP seismic reflection data. Box line thicknesses indicate inferred depth of lake based on seismic reflection data. **(g)** Quantitative lake level curve in black. Dot-dashed

lines indicate lake levels of significance: red, desiccated lake; green, modern lake level; blue, highstand lake level. **(h)** Mean annual insolation curves for June and August (bold) for 2.75°N.

**(i)** Sediment column and sedimentary unit boundaries as described in text.

**Fig. 3.** Upper panels: Legacy multi-channel seismic reflection data across the south basin (Project PROBE profile 84-342). Vertical scale is two-way travel time in milliseconds. Uninterpreted section in uppermost panel; interpreted section in the center panel with major horizons (black horizontal lines) and major faults (black vertical lines). Lower panel is the nearly coincident high-resolution CHIRP seismic line with faults indicated by black lines.

**Fig. 4.** CHIRP seismic lines where key sediment cores were collected. Upper panel displays 46P projected on seismic data. Small black arrows indicate onlapping surfaces discussed in text. Corresponding high-resolution core image and simplified stratigraphic section are at left. Downcore geochemical data are total organic carbon (bold black line) and calculated total carbonate (thin black line), each sampled at 8-cm interval. Lower panel provides the same information for core 4P. The letter “T” followed by a number, which increases with stratigraphic level, denote sequence boundaries names. Named horizons with an underscore and followed by

an additional number denote subsequence boundaries and marker horizons. Named horizons are also described in Table 2.

**Fig. 5.** Down core measures of saturated bulk density, magnetic susceptibility, and organic carbon, in depth, in all three cores illustrating stratigraphic overlap. Overlapping parts of 4P (blue), 14P (purple), and 46P (red). Note that 14P data bridge 1.2-kyr gap between the bottom of 4P and the top of 46P. Black arrows indicate key correlative changes in geophysical or geochemical parameters between cores. Vertical axis is depth in centimeters plotted downcore. Note that vertical axes are set at different scales for graphical clarity.

**Fig. 6.** Radiocarbon dates from three separate piston cores modeled in Bacon (Blaauw and Christen, 2011). Dots indicate average age of core material dated; the color of the dot indicates sample material. Yellow circles are bulk organic carbon, pink circles are bulk inorganic carbon, white circles are macrophytes, green circles are charcoal, dark blue circles are shell material. Error or radiocarbon ages are plotted as brackets on circles. Most errors are within the size of the

circle. Solid lines are best-fit outputs. Dashed lines indicate extremes of possible MCMC model outcomes. Errors on younger dates are smaller than the plotted circles.

**Fig. 7.** Late Holocene (2.2 ka) unconformity (red arrows) in high-resolution seismic data, and its correlative conformable surface at toward the basin center.

**Fig. 8.** (A) Airgun seismic line approximately perpendicular and adjacent to the eastern shoreline displaying progradational internal reflections, interpreted as a paleodelta. Vertical scale is two-way travel time in milliseconds. Location map of trackline is in upper right. (B) CHIRP seismic line coincident with Airgun seismic reflection profile. Vertical scale is two-way travel time in milliseconds. Black box outlines the interpreted buried paleodelta. Black vertical lines are faults. (C) Enlarged view of buried paleodelta. Upper panel is raw profile and lower panel is dimmed profile with interpreted dipping internal reflections.

**Fig. 9.** Uppermost panel is interpreted lake level (black line) of Lake Turkana derived from datasets presented in this study plus shoreline radiocarbon dates from Garcin et al., 2012 (black X). Dashed horizontal lines indicate modern lake level at 360 masl and highstand lake level at

440 masl; lake desiccation is indicated at 250 masl. Panels for Lakes Victoria, Albert, Challa and Tana are relative lake levels as indicated in publications cited in figure (Beuning et al., 1997b; Stager and Johnson, 2000; Talbot et al., 2000; Williams et al., 2006; Lamb et al., 2007; Verschuren et al., 2009; Moernaut et al., 2010; Marshall et al., 2011). Lake Abhe's lake level record in meters above seal level is reconstructed from Gasse et al., 1977.

### **Abstract**

The late Quaternary water level history of Lake Turkana, Kenya, has long-been used as a gauge of the paleohydrology of northern equatorial Africa. However, the atmospheric circulation changes that cause hydrologic variations in this region remain poorly understood. At present, precipitation at Lake Turkana (2° N) is delivered by the twice-annual passage of the Intertropical Convergence Zone, and back-trajectory analysis indicates that virtually all the moisture is sourced from the Indian Ocean. We present a ~20-kyr compound-specific (C<sub>28</sub> *n*-alkanoic acids) hydrogen isotope ( $\delta D_{wax}$ ) record derived from three new, ~10 m sediment cores from Lake Turkana, coupled with an evaluation of the controls on the  $\delta D$  of precipitation ( $\delta D_{precip}$ ), to evaluate changes in precipitation amount and changes in the relative contributions of other moisture sources to this region during the African Humid Period (AHP). We observe abrupt D-depletion associated with the AHP beginning at 13.7 ka and continuing until the ~4ka. Using present-day

relationships between the  $\delta D$  the hydrogen isotope composition and amount of modern precipitation from central Kenya, we estimate the amplitude of possible amount effects for the AHP using quantitative precipitation estimates from a lake basin fill model. Amount effect values of approximately -18‰, -23‰, -25‰, -36‰ were calculated for changes relative to modern in precipitation amounts of 0%, 26%, 40%, and 100%, respectively. After accounting for these effects, precipitation during the AHP is D-depleted relative to a 100% increase in precipitation amount. We suggest this excess in D-depletion is driven by an influx of moisture derived from the Congo Basin, and estimate that at least 45% of the moisture supplied to this part of East Africa during the AHP was Congo-derived. Results from Lake Turkana are consistent with other regional  $\delta D_{wax}$  records from Lake Tana in Ethiopia (12° N) southward to Lake Malawi (9°-14° S), that indicate an eastward migration of the Congo Air Boundary during the AHP, although the timing and magnitude of D-depletion among the  $\delta D_{wax}$  records however suggest Congo Basin influence was not uniform across space and time. These results confirm an important role for both meridional and zonal reorganizations of the atmospheric circulation over East Africa during the African Humid Period.

## 1 Introduction

Extreme fluctuations in precipitation during the late Quaternary in East Africa are evident from lake levels and other proxy records (Johnson et al., 1996; deMenocal, 2000; Lamb et al., 2007; Verschuren et al., 2009; Stager et al., 2011; Garcin et al., 2009, 2012a; Tierney et al., 2011; Junginger et al., 2013; Costa et al., 2014; Morrissey and Scholz, 2014). Geographical coverage of paleo-precipitation data sets is limited however, and available records are mostly from lake basins located in relatively humid regions or from marine sediments that accumulate leaf waxes from vast and often poorly constrained areas. In contrast, Lake Turkana is a large, low elevation lake (360 m asl) in an arid environment, making it extremely sensitive to precipitation changes. This study presents a new 20-kyr record of the hydrogen isotopic composition of terrestrial leaf waxes (*n*-alkanoic acids, hereafter  $\delta D_{\text{wax}}$ ), refining our understanding of the Late Quaternary atmospheric circulation and past climates of East Africa.

Coupled changes in the latitudinal migration of the Intertropical Convergence Zone (ITCZ) and the strength of the African Monsoons are commonly invoked as leading causes of variation in rainfall across tropical East Africa on many timescales, particularly in Northern and Southern Africa where the monsoon limit defines sharp changes in climate regimes (i.e., Castañeda et al., 2009; Nicholson, 2009; Schefuss et al., 2011; Foerster et al., 2012; Junginger et al., 2013). Yet in the present, both meridional changes in the position of the ITCZ as well as zonal changes in the position of the Congo Air Boundary (CAB), a convergence zone between westerly and easterly flows from the Atlantic and Indian Ocean, are important controls on past East African precipitation. In equatorial East Africa, east-

west migration of the CAB since the Last Glacial Maximum ( $\sim 19$  ka; LGM) is thought to play an important role in the variation in equatorial east Africa precipitation, and is thought to have influenced past rainfall changes on many timescales, especially during the African Humid Period (AHP), when many African lakes were at higher levels than today (Liu et al., 2003; Tierney et al., 2008, 2011; Junginger and Trauth, 2013; Junginger et al., 2014; Costa et al., 2014). Recent studies utilizing the hydrogen isotopic ( $\delta D$ ) composition of leaf waxes from terrestrial plants have begun to elucidate changes in the position and intensity of convection within the ITCZ and CAB, and suggest that changes in both precipitation amount and moisture sources are key to interpreting the mechanisms driving African precipitation change over the last  $\sim 30$  ka (Tierney et al., 2008, 2011, 2013; Schefuss et al., 2011; Berke et al., 2012; Costa et al., 2014). Records of the isotopic composition of East African precipitation can be used to reconstruct these processes, yet the controls on isotopic composition of precipitation over East Africa are complex. The hydrogen isotopic composition of precipitation ( $\delta D_{\text{precip}}$ ) can be modified by an “amount effect” (Dansgaard, 1964), in which high rates of precipitation give rise to D-depletion relative to lower rates of precipitation. Changes in precipitation sources, degree of recycling, and transport also play key roles in controlling  $\delta D_{\text{precip}}$ . The hydrogen isotopic composition of terrestrial leaf waxes primarily records changes in the isotopic composition of precipitation, and hence provides information on moisture sources and their variability (Sessions et al., 1999, 2001; Huang et al., 2002, 2004; Sachse et al., 2012; Garcin et al., 2012b). However because evaporation and plant metabolic processes modify the isotopic composition of precipitation, a  $\delta D_{\text{wax}}$  value is not a direct record of the isotope composition of rainfall (Sessions et al., 1999; Huang et al., 2002, 2004; Sachse et al., 2004). Vegetation type and a metabolic difference between  $C_3$  and

C<sub>4</sub> plants also have an effect on the fractionation of hydrogen isotope compositions of organic compounds (Huang et al., 2002, 2004; Chikaraishi et al., 2004).  $\delta^{13}\text{C}_{\text{wax}}$  is useful for constraining past changes in regional vegetation in East Africa, and allows us to constrain changes in the D/H apparent fractionation between plant types allows us to correct for vegetation effects on the  $\delta\text{D}_{\text{wax}}$  record (Sachse et al., 2012).

Here we present new isotopic reconstructions of vegetation and atmospheric processes based upon  $\delta^{13}\text{C}_{\text{wax}}$  and  $\delta\text{D}_{\text{wax}}$  from Lake Turkana, Kenya. We present the first late-Pleistocene to Holocene vegetation record from Lake Turkana based upon  $\delta^{13}\text{C}_{\text{wax}}$ , and use these data to correct for vegetation effects on  $\delta\text{D}_{\text{wax}}$ . We then evaluate past changes in rainfall amount and the moisture sources from Turkana catchment rainfall, as well as other possible influences, on the  $\delta\text{D}_{\text{wax}}$  record. Modern precipitation data from East Africa are used to estimate an amount effect for the Turkana region, providing important constraint on past precipitation variability and moisture source contributed to the AHP. This record provides an important perspective in the understanding of AHP climate dynamics and zonal moisture in East Africa not yet derived from other data sets.

## 2 Study site

Lake Turkana (2-5° N, 36-36.5° E, 360 m asl; Fig. 1) is the largest lake in the Eastern Branch of the East African Rift System. The lake is 250 km long and ~30 km wide with a mean depth of 35 m. The lake is well-mixed due to strong diurnal winds from the southeast, driven by cooling of high topography adjacent to the lake (Hopson, 1982) as well as a persistent unidirectional wind from the northeast, with an average wind speed of 11 ms<sup>-1</sup> (Burlando et al., 2010). The climate in the Turkana region is extremely arid with less than

200 mm yr<sup>-1</sup> of precipitation and over 2300 mm yr<sup>-1</sup> of evaporation at lake level at the bottom of the rift valley (Ferguson and Harbott, 1982; Nicholson et al., 1998). Rainfall over the lake occurs during the twice annual passage of the ITCZ in ~April and ~November. The Omo River enters Lake Turkana at the northernmost shore from the Ethiopian Highlands and provides 80-90% of the hydrological input to the lake (Yuretich, 1979). The Omo River also provides a large amount of the sediment load, especially for the north and central basins (Yuretich, 1979). Lake Turkana is a hydrologically closed basin, with a drainage basin area of ~148,000 km<sup>2</sup> but, at its highstand, Lake Turkana overflows into the White Nile River drainage (Hopson, 1982; Garcin et al., 2009).

The South Basin, where the cores for this study were recovered, reaches 120 m in depth and receives minimal input from the Omo sediment plume (Yuretich, 1979, Cerling, 1986). Organic matter extracted from cores in the South Basin is a mixture of material from aquatic and terrestrial sources, with weight percentages of total organic carbon ranging from ~0.5% to ~7% (Morrissey and Scholz, 2014). The Kerio and Turkwel Rivers drain the areas to the west and south of the lake, and ephemeral rainy-season streams provide the remaining hydrological input.

Vegetation surrounding the modern lake is mostly subdesert steppe and includes *Acacia*, *Commiphora*, *Chenopodiaceae/Amaranthaceae* and *Gramineae* (Hemming, 1972; Vincens, 1982; Mohammed et al., 1995). These plants all use either the C<sub>3</sub> or C<sub>4</sub> photosynthetic pathway; none of the plant groups identified in the region from previous work use Crassulacean Acid Metabolism. No pollen or vegetation information for the AHP is available from Lake Turkana.

### 3 Materials and Methods

#### 3.1 Core Acquisition and Chronology

Three Kullenberg piston cores, Turk10-4P, Turk10-14P, and Turk10-46P, were collected from the South Basin of Lake Turkana in water depths of 52, 56, and 58 m, and are 9.7, 8.5, and 10.6 m in length, respectively (Fig. 1; Morrissey and Scholz, 2014). Twenty-four AMS  $^{14}\text{C}$  samples of bulk organic matter, bulk carbonate, plant material, or shells provided chronologic control, and a Bayesian age-depth program, “Bacon” (Blaauw and Christen, 2011) was used to generate an age model for the composite core record. The three cores were stratigraphically correlated using magnetic susceptibility, gamma ray density and organic carbon content to generate a composite record that spans from  $\sim 20$  ka to  $\sim 0.4$  ka (Morrissey and Scholz, 2014).

#### 3.2 Extraction and Isotope Measurements

We measured the hydrogen isotope composition of the dominant terrestrial homologue ( $\text{C}_{28}$ ) of the long-chain *n*-alkanoic acids, leaf waxes, in 60 sediment samples from these cores. Samples were prepared for isotopic analysis as described in Konecky et al. (2011). Lipids were extracted from sediment samples using a Dionex 350 accelerated solvent extractor. Fatty acids were separated from other lipids using aminopropyl columns, and the fatty acids were methylated using acidified methanol of a known isotopic composition. The resulting fatty acid methyl esters were purified using a Si-gel column prior to isotopic analysis. Samples were analyzed using a gas chromatograph interfaced to a Delta XL isotope ratio mass spectrometer at Brown University. While analyses focused on  $\text{C}_{28}$  *n*-acid, the  $\text{C}_{26}$  homologue was also measured in a subset of samples (Fig. 2). All samples

were measured in duplicate or triplicate, depending upon the amount of sample material available; all  $\delta D_{wax}$  measurements are reported relative to VSMOW and have been corrected for the added methyl group. Measurements made in duplicate have an average difference of 2.2‰; measurements made in triplicate have an average error of 2.2‰ and a maximum error of 4.4‰. The average sampling interval is ~320 yr, however, in samples that date between ~17 and ~13.7 ka, leaf wax concentrations were below reliable detection limits and are not reported. All  $\delta D_{wax}$  values were corrected for the ice volume effects on the isotopic composition of seawater by using the shifts in LR04 benthic oxygen isotope stack (Lisiecki and Raymo, 2005) scaled to hydrogen isotopes, using the D-O relationship of meteoric water assuming a 1‰ enrichment of  $\delta^{18}O$  at the LGM (Schrag et al., 1996).

We also measured the carbon isotopic composition ( $\delta^{13}C_{wax}$ ) of the  $C_{28}$  homologue, as well as the  $C_{26}$  and  $C_{30}$  homologues, on a subset of samples (Fig. 2).  $\delta^{13}C_{wax}$  was measured in duplicate on a Thermo Finnegan Delta XL gas chromatograph-isotope ratio mass spectrometer at Brown University. All  $\delta^{13}C_{wax}$  values are reported relative to VPDB and were corrected for the addition of the added methyl group.  $C_{28}$  *n*-acid measurements had an average  $\delta^{13}C_{wax}$  difference of 0.05‰ and maximum of 0.48‰. The average  $\delta^{13}C_{wax}$  sampling interval is ~800 yr over the whole core.

### 3.3 Backwards Trajectory Models

The NOAA Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT) 4 Model (Draxler and Hess, 1998) was used to determine pathways of moisture transport for precipitation reaching Lake Turkana (Fig. 3). HYSPLIT backwards-models of air mass

trajectories were generated for Lake Turkana for every month for five years (2004–2008) using the NCEP Global Reanalysis dataset (Fig. 3). Models were run in reverse from the location of the South Basin of Lake Turkana (2.6° N, 36.6° E) for 174 hours with a new trajectory started every 6 hours. Monthly rainfall data from 1960-2013 from Lodwar and Nairobi, Kenya were acquired from the NOAA National Climatic Data Center to determine seasonal variations in modern rainfall, and precipitation and hydrogen isotope data from Muguga and Kericho, Kenya for 1967 and 1968 were acquired from the GNIP database (Fig. 1). The same HYSPLIT models were run for the location of Muguga from 2008 to 2011 to determine moisture sources for comparison to instrumental precipitation datasets.

## **4 Results**

### **4.1 Leaf Wax Isotope results**

$\delta D_{\text{wax}}$  values from Lake Turkana sediment average  $-111\text{‰}$ , and vary from  $-144\text{‰}$  during the peak of the African Humid Period (AHP) to  $-69\text{‰}$  during the LGM (Fig. 2). Waxes deposited between the LGM and  $\sim 17$  ka are relatively D-enriched and vary from  $-69\text{‰}$  to  $-104\text{‰}$ . Between  $\sim 17$  and 13.7 ka,  $\delta D_{\text{wax}}$  could not be measured from samples from these cores due to low compound concentrations. This time period corresponds to a period of severely low lake level at Lake Turkana, when total organic carbon values preserved in sediment cores were  $\sim \leq 1\%$  (Morrissey and Scholz, 2014). At 13.7 ka, values near  $-93\text{‰}$  are similar to the LGM, and  $\delta D_{\text{wax}}$  then abruptly shifts to more D-depleted values reaching  $-116\text{‰}$  over an interval of  $\sim 600$  years. From 13.7 ka to  $\sim 6.1$  ka,  $\delta D_{\text{wax}}$  remains depleted, with an average of  $-125\text{‰}$ .  $\delta D_{\text{wax}}$  exhibits several  $\sim 10\text{‰}$  fluctuations during the AHP, as well as a  $\sim 30\text{‰}$  D-enrichment at 8.1 ka. Between 7 and 6 ka,  $\delta D_{\text{wax}}$

gradually become more enriched, then varies between -89‰ and -120‰ with an average of -110‰ until ~1.5 ka. After 1.5 ka,  $\delta D_{wax}$  becomes progressively more enriched towards the top of the record. Values after 1.4 ka are the most enriched since the LGM.

$\delta^{13}C_{wax}$  varies from -33‰ to -20‰ with an average of -28‰ (Fig. 2). Between 19.5 ka and 13.5 ka,  $\delta^{13}C_{wax}$  varies between -22‰ and -27‰. Values are more depleted (-30‰ to -33‰) from 11.4 until 3.6 ka with the exception of an enriched sample (-24‰) at 9.2 ka. After 3.6 ka,  $\delta^{13}C_{wax}$  becomes more enriched reaching values of up to -20‰ at 0.4 ka. The  $\delta^{13}C_{wax}$  of  $C_{26}$  and  $C_{28}$  *n*-acid ( $r^2 = 0.27$ ,  $p = <0.0001$ ) but the number of samples is low ( $n = 19$ ).  $\delta^{13}C_{wax}$  is inversely correlated with  $\delta D_{wax}$  with an  $r^2$  of 0.59 (Fig. S1).

#### **4.2 Backwards trajectory analysis**

Results from HYSPLIT analysis at both Lake Turkana and Muguga indicate that nearly all of the air masses that influence these sites are derived from the Indian Ocean; however, the region of the Indian Ocean from which the air masses are derived differs throughout the year. The two main directions which air masses travel correspond to the two annual African Monsoons experienced by much of the East African tropics. During the April and May rainy season (Fig. 3), air masses are derived from the SE, and enter East Africa near the coast of Mombasa and Dar es Salaam (Fig. 1). During the second rainy season in November and December (Fig. 3), air masses flow from the NE, off the coast of Somalia.

### **5 Discussion**

Our data document very large variations in vegetation, rainfall, and atmospheric circulation over Lake Turkana during the late Pleistocene and Holocene. Below we discuss these data in the context of other regional records of past climate.

### **5.1 Changing Vegetation and its Impacts on $\delta D_{wax}$**

Moisture availability, temperature, and atmospheric CO<sub>2</sub> concentrations are important determinants of the relative abundances of C<sub>3</sub> and C<sub>4</sub> plants in Africa. Of these, precipitation is thought to be the dominant control, due to the strong effects of precipitation on the relative abundances of trees, which are mostly C<sub>3</sub> plants, versus grasses (mostly C<sub>4</sub>) in semi-arid to arid savannahs and steppe (Mohammed et al., 1995). The landscape surrounding Lake Turkana today sustains sparse plant life near the water's edge (Hemming, 1972; Hopson, 1982; Vincens, 1982; Mohammed et al., 1995) and a mix of grasses, chenopods, etc. in the catchment. Our  $\delta^{13}C_{wax}$  data document substantial changes to this community through time.

Depleted  $\delta^{13}C_{wax}$  values near  $\sim 30\text{‰}$  (Fig. 2) indicate C<sub>3</sub> plants were especially prevalent on the landscape during the AHP. This stands in contrast to the present, where C<sub>4</sub> plants dominate and  $\delta^{13}C_{wax}$  values average  $\sim 20\text{‰}$ . The range of values of  $\delta^{13}C_{wax}$  from Lake Turkana is greater than that reported from other locations within East Africa: the overall range in  $\delta^{13}C_{wax}$  values is  $\sim 13\text{‰}$  in Turkana, whereas it is  $\sim 2\text{‰}$  in Lake Malawi  $\sim 6.5\text{‰}$ , at Lake Tana and  $\sim 11.5\text{‰}$  at Lake Tanganyika (Tierney et al., 2010; Konecky et al., 2011; Costa et al., 2014). Indeed, the maximum difference observed at Turkana is comparable to the maximum difference in  $\delta^{13}C_{wax}$  compositions between C<sub>3</sub> and C<sub>4</sub> plants of  $\sim 14.9\text{‰}$  (Smith and Freeman, 2006; Chikaraishi and Naraoka, 2007). The range in values

in the Turkana record indicate a significant shift in vegetation regimes between ~13 to 3.8 ka and suggest a more hospitable environment may have persisted in the Turkana region during the AHP. The  $\delta^{13}\text{C}_{\text{wax}}$  record collected as part of this study is the only early and mid Holocene vegetation proxy derived from the Turkana region to date and indicates large changes in the vegetation of this hyperarid basin during the wet conditions of the African Humid Period.

The  $\delta\text{D}_{\text{wax}}$  and  $\delta^{13}\text{C}_{\text{wax}}$  records derived from the sediment cores are highly correlated ( $r^2 = 0.60$ ) (Fig. 2). While this effect is likely due to the fact that  $\delta\text{D}_{\text{wax}}$  records hydrologic changes that affect plant distribution, it likely also suggests that changes in vegetation affected the hydrogen isotope record. Differing biosynthetic processes between  $\text{C}_4$  and  $\text{C}_3$  plant types can produce D-enrichment of up to 20‰ in environments with 100%  $\text{C}_4$  plants compared to environments with 100%  $\text{C}_3$  plants (Sachse et al., 2012). Changes in the relative abundance of  $\text{C}_4$  versus  $\text{C}_3$  plants can be estimated from  $\delta^{13}\text{C}_{\text{wax}}$  values (Scheffuss et al., 2011; Costa et al., 2014), which vary from approximately -22‰ to -37‰ for  $\text{C}_4$  and  $\text{C}_3$  plants, respectively (Chikaraishi et al., 2004). Variations in  $\delta^{13}\text{C}_{\text{wax}}$  can thus be used to evaluate the influence of these plant types on the  $\delta\text{D}_{\text{wax}}$  record.

The  $\delta\text{D}_{\text{wax}}$  samples with contemporaneous  $\delta^{13}\text{C}_{\text{wax}}$  values were corrected for vegetation type, assuming a maximum 20‰ difference in  $\delta\text{D}_{\text{wax}}$  between  $\text{C}_4$  and  $\text{C}_3$  plants using the same water source (Fig. 4) (Castañeda, et al., 2009). Given this 20‰ difference,  $\delta\text{D}_{\text{wax}}$  from Lake Turkana could potentially vary by up to 17‰, solely due to differences in types of vegetation through time. In particular, the replacement of  $\text{C}_4$  by  $\text{C}_3$  vegetation amplifies the  $\delta\text{D}$  depletion observed during the African Humid Period relative to the LGM and late Holocene at Lake Turkana (Fig. 4). After correction, the full range of vegetation-

corrected  $\delta D_{\text{wax}}$  from Lake Turkana is approximately 70‰, which must reflect changes in the  $\delta D$  of precipitation itself, likely due either to changes in the amount of precipitation or in precipitation sources.

## 5.2 Isotope Climatology

Numerous processes control the isotopic composition of precipitation including rainout and rainfall amounts, moisture source, moisture transport, and evapotranspiration from the landscape and vegetation. While many of these processes cannot be constrained in paleodata, recent work has highlighted the importance of changing moisture sources during past climate changes in East Africa. At present, moisture within air masses from the Congo Basin and the Indian Ocean has different isotopic compositions, which creates spatial variability in the isotopic composition of precipitation across Africa (Rozanski et al., 1993). Due to its proximity to the equator, Lake Turkana in northern Kenya receives rainfall at two different times of the year associated with the twice-annual passage of the ITCZ through the region. HYSPLIT air mass backwards trajectory models show that modern Lake Turkana receives moisture exclusively from the Indian Ocean (Fig. 3). Climate stations near Lake Turkana also receive the majority of their moisture from the Indian Ocean (Figure S3), and hydrogen isotope values of this precipitation have a relatively D-depleted average composition of -13.7‰ in Muguga in central Kenya (Fig. 1) (Rozanski et al., 1993).

The unimodal source stands in contrast to many other sites of previous  $\delta D_{\text{wax}}$  reconstructions from the region that receive moisture from both the Indian Ocean and Congo Basin sources at different times of the year. For instance, Lake Tana in Ethiopia

receives moisture from multiple sources, but during the AHP it received a greater contribution from Atlantic-derived sources (Costa et al., 2014); a study of Lake Challa in central Kenya also suggests an increased influence of an easterly CAB during the AHP (Tierney et al., 2011). A change in source is one possible hypothesis for the AHP D-depletion present in the Turkana record.

A strong inverse relationship between the amount and isotope composition of rainfall has been observed at tropical latitudes (Dansgaard, 1964; Rozanski, et al., 1993). The “amount effect” operates mainly at the level of individual rainfall events, and it is difficult to extrapolate to paleo- or even monthly precipitation records due to the interactions between moisture transport, rainout, and local rainfall amounts. However, the hydrogen isotope compositions of monthly precipitation for 1967 and 1968 from Muguga and Kericho, Kenya, south of Lake Turkana, are inversely correlated ( $r^2 = 0.1788$ ,  $p = 0.02$ ,  $n = 30$ ) (S2) to monthly precipitation amounts. Muguga, like Lake Turkana, receives all of its precipitation from Indian Ocean-derived moisture sources. The sources of moisture and seasonality are the same for Lake Turkana and Muguga (Fig. 5); this suggests that an amount effect likely exists at Lake Turkana, as is common of many regions in the tropics (Dansgaard, 1964; Rozanski et al., 1993) (Fig. 5). To approximate the possible impacts of an amount effect on the  $\delta D_{\text{wax}}$  record from Lake Turkana, a cumulative total of monthly  $\delta D$  values was derived from weighted monthly precipitation at Muguga (S Table 1). The month with the least amount of rain (July) was then subtracted from this amount to yield the amplitude of D-depletion in precipitation produced by rainfall amounts on a monthly basis. The computed amplitude for modern rainfall amount effect is  $\sim 18\text{‰}$  per month (S Table 1).

Multiple lake level reconstructions derived for Lake Turkana indicate that lake level was much higher during the AHP (Halfman and Johnson, 1988; Garcin et al., 2009, 2012a; Morrissey and Scholz, 2014). While the amount of precipitation increase that caused basin filling during this time period is not precisely known, a recent modeling study of paleo Lake Suguta, located in the valley immediately south of Lake Turkana that shares a similar AHP lake level history, indicates a minimum 26% increase in precipitation is required to fill Lake Suguta, and a maximum increase of 40% may have occurred during the peak of the AHP (Junginger and Trauth, 2013). These calculated percentages were used to estimate possible isotope depletion resulting from an increase in precipitation amount at the Turkana area during the AHP (Fig. 4). Increases in precipitation of 26% and 40% (relative to ~200 mm modern accumulation) at Lake Turkana correspond to an additional ~52 mm and ~80 mm of rainfall, respectively, and  $\delta D$  depletion of -23‰ and -25‰. These were each applied to the vegetation-corrected dataset. An extreme case of a 100% precipitation increase (-36‰) was modeled for comparison. Calculations with both the 26% and 40% increases in precipitation yield reasonable results (Fig. 4) as neither yields AHP isotope values more enriched than modern values. Yet even after this calculation, the AHP appears D-depleted and this residual depletion is likely due to change in moisture source.

#### **5.4 Changes in Moisture source to Lake Turkana**

The vegetation-corrected  $\delta D_{wax}$  values vary by more than 70‰ between the relatively enriched values around the LGM and depleted values during the AHP, and the amplitude of change in  $\delta D_{wax}$  is greater than the most liberal realistic estimations of an amount effect. While the amount effect is very difficult to constrain on modern, let alone

paleo times-scales, this suggests that there must be another cause for D-depletion during the AHP. We suggest that the eastward movement of the Congo Air Boundary may explain the severely depleted  $\delta D_{\text{wax}}$  values at Lake Turkana during the AHP, due to transport of Atlantic moisture via the Congo Basin.

Sources of moisture over East Africa include the Indian Ocean, the Atlantic Ocean by way of West Africa, or Mediterranean, Red Sea and Gulf of Aden sources (Camberlin et al., 2001; Castañeda et al., 2009; Gimeno et al., 2010; Tierney et al., 2011, 2013; Costa et al., 2014). These different sources may provide precipitation to different areas at various times of the year, and account for differing percentages of annual cumulative rainfall (Levin et al., 2009; Costa et al., 2014). Regions closest to the eastern coast of the continent rely on monsoonal rains derived from the Indian Ocean, and HYSPLIT modeling indicates Lake Turkana's moisture is derived from the Indian Ocean-derived monsoons. However, sites further to the west receive significant contributions of moisture from the Atlantic Ocean. These air masses traverse the heavily vegetated Congo Basin and West African lowland rainforests, where high rates of transpiration result in minimal isotopic distillation and relatively enriched water vapor. However, this moisture becomes D-depleted as it moves out of the Congo Basin over drier land to the East African Rift, resulting in a D-depleted isotopic composition distinguishable from other East African moisture sources (Konecky et al., 2011; Tierney et al., 2011; Costa et al., 2014).

Based upon our estimates of the amount effect, changes in moisture source may have had an effect of up to -18‰ on the  $\delta D_{\text{wax}}$  record in Turkana. Other studies suggest that a change in moisture source caused changes in  $\delta D_{\text{wax}}$  isotope compositions over time at locations in East Africa (e.g. Costa et al., 2014). Significant depletion at Lake Tana in the

Ethiopian Highlands during the AHP is attributed to eastward movement of the CAB for several thousand years, allowing more Congo-derived moisture to contribute to the rainfall in the Tana region (Costa et al., 2014). The study from Lake Tana used modern rainfall amounts from different regional sources to calculate a -4‰ change with a 30% increase in Congo-derived moisture (Costa et al., 2014). To use this value to explain the residual depletion amount of -6‰ to -18‰ for the Lake Turkana record, (Fig. 4) the percentage of moisture from a Congo source would have to account for a higher percentage of precipitation than at Lake Tana. It is, however, difficult to explain an -18‰ or higher D-depletion at Turkana using the relationship developed at Lake Tana, as it requires greater than 100% Congo-derived moisture increase. Further modification of the moisture source as it moves eastward may explain the elevated D-depletion, such as additional rainout (relative to modern). Lake Turkana is also farther east than Lake Tana, suggesting larger fractionation of the moisture source is possible as it moves across land. Additionally, the area surrounding Lake Turkana is much drier, which enhances distillation, leading to enhanced D-depletion.

Today Atlantic-derived air masses do not provide significant moisture to precipitation in the vicinity of Lake Turkana. Most rainfall associated with Atlantic moisture falls over and around the Congo Basin (Fig. 1) (Schefuss et al., 2005; Tierney et al., 2008), in the western rift valley, or on high elevations to the north, such as the Ethiopian Highlands (Levin et al., 2009; Costa et al., 2014). Past studies of other lakes in the East African Rift System (EARS) suggest that depleted  $\delta D_{\text{wax}}$  during the AHP was mainly due to increased precipitation (Berke et al., 2012). Berke et al. (2012) argue that more significant depletion at Lake Victoria during the AHP was due to increased precipitation rather than

input from a more depleted precipitation source, because the high mountains to the west of Lake Victoria would have prevented eastward migration of the Congo air masses. However, in the present high seasonal precipitation rates have been documented in association with strong westerlies produce localized convergence in modern climatological studies at Lake Victoria (Nicholson, 1998), and other studies suggest that the CAB migrated far enough eastward during the AHP to influence not only Lake Victoria, but also lakes and regions in the Eastern Branch of the EARS as far away as Mt. Kilimanjaro (Tierney et al., 2011; Junginger et al., 2014; Costa et al., 2014). The  $\delta D_{wax}$  record from Lake Turkana supports the inference for significant influence from Congo-derived moisture during the AHP as has been suggested by studies in the past (Ricketts and Johnson, 1996; Morrissey and Scholz, 2014), and further suggests that this moisture source may have been large, in not dominant, in the Turkana basin. The additional precipitation source allowed Lake Turkana to overflow for several thousand years during the early Holocene and provided an input to the White Nile River (Morrissey and Scholz, 2014).

## **5.5 Insolation variability and long-term climate changes**

High precipitation in Northern and Eastern Africa during the AHP occurred during periods of increased northern hemisphere summer insolation (Fig. 6) (deMenocal et al., 2000; Tierney et al., 2008, 2011; Berke et al., 2012; Costa et al., 2014). The long-term precipitation changes as indicated by  $\delta D_{wax}$  from Lake Turkana also follow boreal summer insolation changes; however, there are some important differences in the onset and termination of increased moisture observed in this data set relative to other regional records. Relatively depleted  $\delta D_{wax}$  values of  $\sim -140\text{‰}$  occur from Turkana between 11 and

8.2 ka, while peak insolation in low latitudes of the Northern Hemisphere occurred at 11.1 ka. The most depleted values occur at 8.4 ka, nearly three millennia after insolation began to decrease. This may suggest that an unfavorable atmospheric configuration may have deprived the area of precipitation at times of peak insolation or a contribution of nonlinear feedbacks associated with ecological turnover resulted in a lagged response of regional precipitation to insolation forcing.

The offset between peak insolation and peak isotope depletion may also be due to the ambiguity in relative contributions between moisture source and precipitation amount over time. While we suggest that both of these factors affected the  $\delta D_{\text{wax}}$  record preserved at Lake Turkana, as highlighted above the relative differences in the effect of one or the other are difficult to separate. The model presented here suggests that at the time of initial depletion, both source and amount also changed, however that may not actually be the case. For instance, the intensification of the monsoons and increase in rainfall amount may have initially caused D-depletion at 13.7 ka, the influence of the CAB migration may not have occurred until later when peak depletion is seen at 8.4 ka instead of during peak insolation. This would imply that different climatological forcings and/or processes cause migration of the ITCZ and of the CAB during the AHP.

## **5.6 Regional variation during the AHP**

The  $\delta D_{\text{wax}}$  records collected from East African lakes show a delay in the timing and a decrease in magnitude of change in a south- and eastward direction (Fig. 6) associated with the onset of the AHP. The initial and most dramatic D-depletions associated with the African Humid Period occurs at Lake Tana (12° N) where  $\delta D_{\text{wax}}$  shifts from -84‰ to -

163‰ between 13.6 and 11.6 ka (Costa et al., 2014) and at Lake Turkana (2° N) with a shift from -93‰ to -131‰ between 13.7 and 12.7 ka. While slight depletions occur at Lakes Challa and Tanganyika as early as 15 ka, the largest amplitude depletions do not occur until after YD enrichment (Tierney et al., 2008; Tierney et al., 2011). At Lake Challa (3° S), depletion from -81‰ to -116‰ occurs between 12.2 and 11.4 ka (Tierney et al., 2011) and Lake Tanganyika (6° S) follows at 11.8 ka with depletion from -95‰ to -129‰ (Tierney et al., 2008). Lake Malawi (10° S) shows negligible response to AHP forcing (Konecky et al., 2011). Farther to the east, a  $\delta D_{\text{wax}}$  record from the Gulf of Aden, thought to record  $\delta D_{\text{precip}}$  over Somalia and the Afar, displays an onset of D-depletion that is similar in timing but of much lower magnitude ( $<-35\text{‰}$ ) compared to Lakes Tana and Turkana (Tierney and deMenocal, 2013; Costa et al., 2014).

Similar variability occurs at the termination of the AHP. Values at Lake Tana are abruptly enriched to late Holocene values at  $\sim 7.5$  ka (Costa et al., 2014), Turkana experiences a more gradual enrichment from 7.5 to 5.8 ka, followed by further enrichment during the late Holocene. Challa's enrichment does not occur until  $\sim 5$  ka (Tierney et al., 2011), as does late Holocene enrichment at Lake Tanganyika (Tierney et al., 2008). Waxes in the Gulf of Aden remain D-depleted until  $\sim 4$  ka however, which is more similar to the record from Lake Turkana.

Hydrogen isotopic records that record the African Humid Period across East Africa reveal considerable variability in the amplitude and timing of isotope fluctuations, and therefore in the regional climate changes that caused the AHP. The Turkana  $\delta D_{\text{wax}}$  values vary from -93‰ to -137‰ from the onset of the AHP at  $\sim 13.7$  ka to the peak of the AHP at  $\sim 10$  ka. At Lake Tana in the Ethiopian Highlands, and in the Gulf of Aden, the transition

from D-enriched to D-depleted values is nearly synchronous with initial D-depletion at Lake Turkana (Fig. 2) at  $\sim 13.5$  ka. However, these records differ substantially in their amplitudes, with Lakes Tana and Turkana displaying a much larger signal than the Gulf of Aden. This could reflect a stronger contribution of Congo-derived moisture to Tana and Turkana, as the Ethiopian highlands should limit moisture transport from westerly sources to Somalia. Hydrogen isotope values from Lake Tanganyika were already moderately depleted at the time (Tierney et al., 2008), while Lake Challa, which has a comparatively small  $\delta D_{\text{wax}}$  signal during the AHP, was already relatively D-depleted at the onset of the AHP and remained D-depleted until  $\sim 12$  ka, after which it became enriched (values as enriched as  $-80\text{‰}$ ) for a few hundred years (Tierney et al., 2011). The new Turkana data support the theory that the CAB may have migrated seasonally at least as far east as the Kenyan Rift area at the onset of the AHP. D-depleted values that persist during the interval from 13.7 to at least 6 ka require Congo Basin moisture contributions to Lake Turkana and the Kenyan Rift, however the relative contribution of Congo- versus Indian Ocean sources likely fluctuated over the time period as evidenced by fluctuations in  $\delta D_{\text{wax}}$  values throughout the time period. Alternatively, precipitation amount was less at times as suggested by fluctuations in the  $\delta D_{\text{wax}}$  values.

Through the mid to late Holocene,  $\delta D_{\text{wax}}$  values at Lake Turkana slowly become more enriched. The magnitude of change in  $\delta D_{\text{wax}}$  from the AHP to present is much less at Turkana when compared to Lake Tana (Costa et al., 2014), and the transition at Turkana is more gradual. This trend at Turkana is similar in the timing of the transition in the  $\delta D_{\text{wax}}$  record from the Gulf of Aden (Tierney and deMenocal, 2013), which suggests the Kenyan Rift as well as coastal regions of Kenya and Somalia remained wetter through the mid-

Holocene. Lake Challa and Lake Tanganyika also remain relatively depleted until  $\sim 6$  ka (Tierney et al., 2011; Tierney et al., 2008). This may suggest a sustained contribution from a southward-shifted, Congo-derived source or gradually diminishing precipitation amounts due to southward ITCZ migration and weakening monsoons through the mid-Holocene than sites to the north. Presently available data cannot quantify these influences, however the spatial variability observed in the records suggests both variability in both the timing and relative contributions of changes in precipitation amount and Congo-derived moisture sources.

Precipitation changes associated with the AHP appear to be temporally and geographically transgressive, based on these records, and the abruptness of precipitation change varies among locations. deMenocal et al. (2000) attribute abrupt responses at the onset and end of the AHP to insolation forcing plus the effects of non-linear feedbacks such as vegetation changes. Others argue that presence or lack of contribution from moisture west of the CAB can enhance abrupt changes seen in  $\delta D_{wax}$  (Tierney et al., 2008; Tierney et al., 2011; Costa et al., 2014). The  $\delta D_{wax}$  record from Lake Turkana suggests that the onset of increased precipitation was abrupt, occurring over just centuries, however the end of the AHP was gradual. The high correlation between the  $\delta^{13}C_{wax}$  and  $\delta D_{wax}$  records from Lake Turkana suggests that vegetation feedbacks were likely important in the abrupt response to insolation forcing at the onset of the AHP. However, the persistent correlation between the two isotopes through the gradual end to the AHP suggests that vegetation was sustained after insolation decreased. Since the migration of the ITCZ and monsoonal moisture is more closely coupled to insolation changes than the movement of the CAB, the

sustained vegetation and persistent depletion in  $\delta D_{\text{wax}}$  at the end of the of the AHP is likely due to sustained contribution from Congo-derived moisture.

## 5.7 Northern latitude teleconnections

Between 8.4 and 8.1 ka, there is an enrichment of  $\sim 45\text{‰}$  in the  $\delta D_{\text{wax}}$  values at Lake Turkana. This is close in timing to a significant enrichment of  $\sim 55\text{‰}$  at Lake Tana that occurred between 8.5 and 7.8 ka (Costa et al., 2014). This enrichment is short lived at Lake Turkana, with values returning to background depleted values of less than  $-120\text{‰}$  by  $\sim 7.5$  ka. The enrichment may be associated with the 8.2 ka event described at in high latitude ice cores (Alley et al., 1997), and Junginger and Trauth (2013) and Costa et al. (2014) suggest the CAB may have been forced south- and east due to the intensified NE winds.

Paleoshorelines below the highstand sill in the South Basin of Lake Turkana are dated to approximately the same time period, which suggest lake level was not at highstand for this interval during the AHP (Garcin et al., 2012a). The  $\delta D_{\text{wax}}$  enrichment further confirms a reduction in precipitation in the region during this short-lived lake level lowstand. The short-term signals observed in the Lake Turkana  $\delta D_{\text{wax}}$  record suggest a possible teleconnection between high latitude climate phenomenon and tropical climate processes.

## 6 Conclusions

- $\delta D_{\text{wax}}$  values fluctuated by an amplitude of  $74\text{‰}$  between the relatively D-enriched values around the LGM and D-depleted values during the AHP. This amplitude exceeds that of most other  $\delta D_{\text{wax}}$  records from East Africa indicating significant change in precipitation since the LGM.

- The CAB does not migrate far enough eastward to allow Congo basin-derived moisture to Lake Turkana today, and the lake instead relies on moisture from the African Monsoons.
- HYSPLIT backwards modeling of air mass trajectories indicate that modern precipitation at Lake Turkana is derived exclusively from the Indian Ocean.
- Modern seasonal Kenyan precipitation amount correlates with isotopic changes. D-enrichment of precipitation of up to  $\sim 25\text{‰}$  occurs during months of high precipitation, suggesting a significant amount effect could potentially account for amplitude change in the  $\delta D_{\text{wax}}$  paleorecord from Lake Turkana.
- Fluctuations in the hydrogen isotope composition of leaf waxes are in part due to changes in vegetation turnover between  $C_3$  and  $C_4$  plants during extreme climate changes in the Turkana region. During the AHP, both carbon and hydrogen isotopes are more depleted, suggesting that  $C_3$  plants likely dominated the landscape during this time.
- During the AHP ( $\sim 14 \text{ ka} - 6 \text{ ka}$ ), the CAB migrated at least as far as central Kenya for most of the duration; however enriched  $\delta D_{\text{wax}}$  at  $8.1 \text{ ka}$  interrupt this period of depletion, suggesting a reduction in CAB influence or an extreme alteration of the isotope composition of the CAB air mass. These could be related to high latitude climate teleconnections in the EAR in the late Quaternary or changes in SST gradients in the western Indian Ocean.
- The onset of the AHP signal in the  $\delta D_{\text{wax}}$  is rather abrupt, occurring over just a few centuries, and is likely due to insolation-driven increased rainfall and vegetation feedbacks as indicated by highly correlative  $\delta D_{\text{wax}}$  and  $\delta^{13}C_{\text{wax}}$  records. The

termination of the AHP is much more gradual than at other places in East Africa, starting at about 8 ka and reaching late Holocene average values at ~4 ka, and is likely due to sustained contributions from Congo-derived moisture.

- Differences in time of onset, amplitude, duration, and time of termination of AHP moisture among East African  $\delta D_{\text{wax}}$  records suggest the AHP was a time transgressive event that had variable influence across the region.

## **7 Acknowledgements**

We thank the government of Kenya for research permissions. Financial support was provided by the sponsors of the Syracuse University Lacustrine Rift Basins Research Program. We thank the National Oil Corporation of Kenya for assistance during field operations. The authors thank the people of Loiyangalani and the Turkana Rift Valley, for their cooperation, assistance, and hospitality during multiple field seasons at Lake Turkana. We would also like to thank Dr. Rafael Taroza, Dr. Bronwen Konecky, Lily Cohen, and Kassandra Costa for assistance with sample preparations and laboratory procedures at Brown University.

## Figures

**Fig 1.** Location Map. **(A)** Africa with rainy season (April and November) locations of the ITCZ and the CAB. Black box locates Lake Turkana. **(B)** Lake Turkana and the surrounding topography. Bathymetry contour interval is 20 m. Black box locates the South Basin. **(C)** South Basin of Lake Turkana with core locations marked by black circles. **(D)** East Africa regional map with relevant locations identified: 1. Lake Malawi, 2. Lake Tanganyika, 3. Lake Tana, 4. Lake Victoria, 5. Lake Turkana, 6. Muguga, Kenya, 7. Mombasa, Kenya 8. Dar es Salaam, Tanzania, 9. Lake Challa.

**Fig. 2.** Isotope data. Upper panel: Mean values of  $\delta D_{wax}$  values of the  $C_{28}$  homologue (black circles) from the composite sediment record. Gray error envelope is  $1\sigma$  for samples run in triplicate and the range of values for samples run in duplicate. Lower panel: Mean  $\delta^{13}C_{wax}$  values (black circles) of a subset of samples from the composite sediment record; all were run in duplicate. Error bars span the range of values. The  $\delta^{13}C_{wax}$  measurements of the  $C_{26}$  and  $C_{30}$  homologues are in gray. Black triangles denote locations of samples utilized for  $^{14}C$  dating.

**Fig. 3.** Backwards trajectory models. NOAA HYSPLIT backward trajectory models for Lake Turkana using NCEP Reanalysis data between 2003-2008. Trajectories are color-coded by month. Lake location indicated by rectangle. Lake Turkana presently receives all of its moisture from Indian Ocean sources, and not from the Atlantic Ocean/Congo Basin.

**Fig. 4.** Isotope corrections. Black data points and line represent ice volume corrected  $\delta D_{wax}$  values that correspond to  $\delta^{13}C_{wax}$ . Dark green data points and lines represent  $\delta D_{wax}$  values corrected for vegetation type based on  $\delta^{13}C_{wax}$  values. The four areas represent the amount effect estimated by four different percentages of increased rainfall and modern isotope data. The darkest blue represents modern rainfall (0% increase), light blue represents the amount effect for a 26% increase in rainfall, medium blue represents the amount effect for a 40% increase in rainfall, and green represents 100% increase in rainfall.

**Fig. 5.** Kenya rainfall data. Upper panel: Monthly average  $\delta D$  of precipitation at Muguga (Nairobi), Kenya during 1967 and 1968 (black dots) and rainfall amounts (grey bars) (IAEA/WMO, 2013). Lower panel: Mean precipitation amount and  $1\sigma$  errors (NOAA/NCDC, 2014) at the Jomo-Kenyatta International Airport in Nairobi between 1960-2013 (light gray bars), and at Lodwar, a town west of Lake Turkana, between 1960-2013 (black bars); error bars are  $1\sigma$ .

**Fig. 6.** African  $\delta D_{wax}$  records.  $\delta D_{wax}$  records from East African lakes; all data plotted at the same scale, and arranged from north to south; data from: Lake Tana (Costa et al., 2014), Gulf of Aden (Tierney and deMenocal, 2013), Lake Turkana (this study), Lake Challa (Tierney et al., 2011), Lake Tanganyika (Tierney et al., 2008), and Lake Malawi (Konecky et al., 2011)

## 8 Supplementary info

**Supplementary Figure 2.** Amount effect correlations. Linear correlations of the observed amount effects at Muguga, Kenya and Kericho, Kenya based on modern isotope and precipitation data. Upper most plot is data from Kericho. Middle plot is data from Muguga. Lower plot is both locations plotted together.

**Supplementary Figure 3.** Backwards trajectory models. NOAA HYSPLIT backward trajectory models for Muguga, Kenya using NCEP Reanalysis data between 2003-2008. Trajectories are color-coded by month.. This location is Location indicated by rectangle. Like Lake Turkana, Muguga, Kenya presently receives all of its moisture from Indian Ocean sources, and not from the Atlantic Ocean/Congo Basin. Precipitation isotope values are used from this location to extrapolate information about Lake Turkana

**Supplementary Figure 4.** Mean values of  $\delta D_{wax}$  values of the  $C_{28}$  homologue from the composite sediment record highlighted by core from which they were derived.

#### **Abstract**

The precipitation-evaporation balance of a lake system is closely related to its heat budget. To attempt to quantify changes in temperature through the onset and termination of the African Humid Period, the paleotemperature proxy TEX<sub>86</sub> was used to generate a 14-kyr record of lake surface temperatures for Lake Turkana. This biomarker and related measures are now routinely used to reconstruct regional and high-latitude paleotemperatures from the oceans and other continental systems, including other large African lakes. TEX<sub>86</sub> temperatures from Lake Turkana from 14 to 0.4 ka are variable and range from 24.3 °C to 28.6 °C, with a mean of 25.9 °C. There is a long-term trend within the temperature record that follows mean northern hemisphere peak summer insolation, and a mean temperature of 26.2 °C during the early Holocene decreases to 25.7 °C during the late Holocene. A decade-to-century scale fluctuation of ~1 °C persists throughout most of the record; analyses of elemental ratios from the sediment cores suggest this high-frequency

variation is likely related to lake mixing processes that overprint the regional climate signal. While this was an unexpected result from this analysis, it shows that this proxy may have limitations in its application to well-mixed, arid-land lake systems. High-frequency variation in temperatures remains close to the mean for duration of the record, which may partially be attributed to the evaporation response of this lake system.

## 1 Introduction

Much of the world's freshwater is located in the watersheds of large lakes, and several of the largest lakes are located in tropical East Africa. Lake water volumes fluctuated significantly during times of changing climate, in some instances leading to complete lake desiccation (Johnson et al., 1996; Scholz et al., 2007; Lamb et al., 2007; Morrissey and Scholz, 2014). In a time of accelerating climate change, and with the likelihood of future temperature increases, analyses of the past temperature and evaporation changes and links to large lake hydrology are particularly important for the riparian populations of the desert region of Turkana. The paleotemperature proxy TEX<sub>86</sub> quantifies the relative abundances of glycerol dialkyl glycerol tetraethers (GDGTs) preserved in sediments, and helps evaluate changes in temperature of the lake surface waters.

Lake surface paleotemperature reconstructions from East African lakes reveal significant variations in the amount of warming since the Last Glacial Maximum (LGM), as well as warming associated with the early Holocene African Humid Period (AHP) (Powers et al., 2005; Tierney et al., 2008; Berke et al., 2012a), a time when the East African tropics experienced increases in rainfall and relative humidity. Lakes Tanganyika and Victoria show ~2 °C of warming at the onset of the AHP, following northern hemisphere peak summer insolation trends (Tierney et al., 2008; Berke et al., 2012b). Lake Malawi however, does not display a temperature increase at the onset of the AHP (Powers et al., 2005) because at its location at 12° S of the equator it did not experience more humid conditions in the early Holocene as did much of North Africa. Earlier studies from Lake Turkana suggest a thermal maximum during the mid-Holocene (Berke et al., 2012a). The lake

surface temperatures in Lakes Malawi and Tanganyika respond to high latitude climate shifts such as the Younger Dryas (YD) and Heinrich Event 1 (Powers et al., 2005; Tierney et al., 2008), whereas the YD response at Lake Victoria is comparatively short-lived (Berke et al., 2012b). The events and trends captured within lake surface temperature reconstructions are variable and may represent high latitude teleconnections or capture local atmospheric and paleohydrological changes.

The environment at Lake Turkana is unique, as it is one of the largest lakes in the world but it is situated in a low elevation, near-equatorial desert. It receives 200 mm yr<sup>-1</sup> of precipitation onto its surface, in contrast to other African Great Lakes such as Lake Tanganyika or Malawi, which receive upwards of 1000 mm yr<sup>-1</sup> (Nicholson, 1996). Its fluctuation in annual temperature is minimal, and the annual evaporation amount is extremely high at 2300 mm yr<sup>-1</sup> (Ferguson and Harbott, 1982). Additionally, the water column of Lake Turkana is well-mixed, setting it apart from the deep, stratified lakes of the Western Branch of the East African Rift System. Whereas the modern Turkana rift valley is hyper-arid, and the lake is slightly saline and hydrologically closed, the climate at Lake Turkana fluctuated significantly in the past. During the early Holocene, the lake level was high and overflowed to the White Nile River system (Owen et al., 1982; Halfman et al., 1988; Garcin et al., 2012; Morrissey and Scholz, 2014). When analyzing changes in precipitation and paleohydrology, the timing and duration of temperature changes are also important considerations, especially in an extreme environment such as the Turkana region where the riparian population of >700,000 relies on lake fishing as a key food source, and the water for grazing and watering of livestock as well as for irrigation. A new, 14-kyr lake surface temperature record for Lake Turkana is presented here, developed

using the TEX86 technique, in order to analyze fluctuations in regional temperature and hydrology in an area of extreme climate and over an interval that experienced dramatic regional climate change.

## **2 Geologic Background**

Lake Turkana (2-5° N, 36-36.5° E, 360 m asl; Fig. 1) is the largest lake in the Eastern Branch of the East African Rift System at ~250 km long and ~30 km wide, and is a hydrologically closed basin in an arid environment. Precipitation at Lake Turkana occurs during the twice a year passing of the Intertropical Convergence Zone (ITCZ) in ~April and ~November. The lake is well-mixed due to strong diurnal winds from the southeast driven by cooling of high topography adjacent to the lake (Ferguson and Harbott, 1982), from a persistent unidirectional wind from the northeast with an average wind speed of 11 m s<sup>-1</sup> (Burlando et al., 2010), and because the relatively shallow mean depth of 35 m (Yuretich, 1979). The Turkana area in northern Kenya is one of the hottest regions on the planet (Passey et al., 2010) with mean annual air temperatures at Lake Turkana of more than 29 °C (Fig. 2). Monthly average maximum temperatures in 2013 were at least 33.5 °C, and monthly average minimum temperatures were no lower than 23.8 °C (Fig. 2).

The Omo River provides a large amount of the sediment load, especially in the northern part of the lake (Yuretich, 1979). The South Basin, where these samples were collected, is 120 m at the deepest point and receives minimal sediment input directly from the Omo River (Yuretich, 1979, Cerling, 1986) (Fig. 1). The Omo River provides 80-90% of the hydrological input to the lake from the Ethiopian Highlands (Yuretich, 1979) and enters Lake Turkana at the northern shore of the lake at the Ethiopian border. The area of the

drainage basin is  $\sim 148,000 \text{ km}^2$  (Ferguson and Harbott, 1982; Garcin et al., 2012), and includes the Kerio and Turkwel Rivers to the west of the lake, as well as ephemeral rainy-season streams (Fig. 1).

Water temperature in Lake Turkana varies throughout the year both laterally and with depth (Fig. 3) (Ferguson and Harbott, 1982). Due to strong, persistent winds in the area and the straight shoreline morphology created by E-W structural deformation, surface currents develop and contribute to the mixing of the water column (Yuretich, 1979). Surface temperatures in the South Basin are generally lower than temperatures in the North Basin (Fig. 3), and temperatures are 1-3.5 °C lower in the peak northern hemisphere summer months than in the spring or fall (Ferguson and Harbott, 1982). The seasonal water temperature trends are similar to the trends observed in monthly air temperatures recorded at the lakeshore (Ferguson and Harbott, 1982; NOAA/NCDC, 2014) (Fig. 2).

### **3 Materials and Methods**

#### *3.1 Sample collection and sediment core chronology*

Fifty-three paleotemperatures that span the period  $\sim 14 \text{ ka}$  to  $0.4 \text{ ka}$  were produced using organic rich sediments (1-6% Total Organic Carbon) from Lake Turkana sediment cores (Fig. 4). Three Kullenberg piston cores, Turk10-4P, Turk10-14P, and Turk10-46P, were collected from the South Basin of Lake Turkana in water depths of 52, 56, and 58 m, and are 9.7, 8.5, and 10.6 m in length, respectively (Fig. 1). The cores were subsampled at an interval of  $\sim 240$  years to generate a lake surface temperature record using the TEX<sub>86</sub> paleotemperature proxy (Schouten et al., 2002). The three cores were stratigraphically correlated using magnetic susceptibility, gamma ray density, and total organic carbon

content, and together provide a continuous composite sediment record (Morrissey and Scholz, 2014).

The chronology for this record was developed using 24 AMS  $^{14}\text{C}$  samples. Dated material consisted of bulk organic matter of mixed lacustrine and terrestrial origin, bulk carbonate from water column precipitation, and detrital carbonate from surface runoff, discrete macrophyte specimens, or ostracode and gastropod shells (Morrissey and Scholz, 2014). A flexible, Bayesian age-depth program, “Bacon” (Blaauw and Christen, 2011) was used to generate an age model for the composite core record. Morrissey and Scholz (2014) present detailed information on the stratigraphic framework, lithology, and geochemistry of the composite core record.

### *3.2 Lipid extraction and $\text{TEX}_{86}$ Temperature proxy analysis*

The total lipids (TLE) were extracted from individual freeze-dried and homogenized sediment samples via DIONEX<sup>TM</sup> accelerated solvent extraction, using Dichloromethane (DCM):Methanol (9:1). The polar and apolar fractions of the TLE were purified using activated alumina elution columns. Columns were precleaned with DCM:Methanol (1:1) and Hexane:DCM (9:1) solutions. The apolar fraction was then eluted using the Hexane:DCM (9:1) solution, and the polar fraction was eluted with the DCM:Methanol (1:1) solution, each into separate vials. The Glycerol Dialkyl Glycerol Tetraethers (GDGTs) quantification of the purified polar fraction of the TLE used for  $\text{TEX}_{86}$  analysis was carried out using a high performance liquid chromatograph/positive ion atmospheric chemical ionization mass spectrometer (HPLC/APCI-MS) on an Agilent 1200 HPLC/MS

system. Replicate analyses produce results within  $\pm 0.1$  °C. Ratios of GDGTs I-IV were used to calculate the TEX<sub>86</sub> temperatures (Schouten et al., 2002).

### *3.3 TEX<sub>86</sub> Temperature proxy calibration*

Multiple calibration equations have been developed for the application of TEX<sub>86</sub> temperature reconstructions in different environments (i.e. Schouten et al., 2002; Powers et al., 2005, 2010; Kim et al., 2008, 2010; Tierney et al., 2010). Powers, et al. (2005, 2010) developed and later modified a calibration for the use of the TEX<sub>86</sub> value for temperature reconstruction in large lakes. Tierney, et al. (2010) developed a proxy that used a larger dataset of African lakes of varying sizes, volumes and water chemistries. Kim et al. (2008) produced a global marine core top calibration study that includes 287 different samples. This calibration was later revised to include a subset of 255 core top samples specifically for a high temperature calibration, that is suggested for use in tropical environments (Kim et al., 2010). For this Lake Turkana study, several calibration equations were applied to the dataset (Fig. 5). The results from the large lake calibrations (Powers et al., 2005, 2010; Tierney et al., 2010) yield temperatures that are systematically low compared to modern Lake Turkana surface water temperatures (Fig. 5). There was minimal difference in the results between the Kim et al. (2008) and Kim et al. (2010) calibration equations. The temperatures that are produced using the open-marine core top calibrations (Kim et al., 2008, 2010) are most similar to modern temperature values (Fig. 5). Lake Turkana is well mixed and lacks a chemocline and permanent anoxic bottom waters that occur in many large tropical lakes. Accordingly, the populations of crenarchaeota present in Lake Turkana may be more similar to those of marine settings than of large lakes. Lake Turkana is also

slightly saline (1.5 ‰), which is more similar to marine settings than large freshwater lakes; however a study conducted by Wuchter et al. (2004) determined no difference in GDGT distributions in mesocosm experiments of salinities of 27‰ vs. 35‰. Thus, the mild salinity of the water in Lake Turkana is not likely a factor in calibration selection. Additionally, previous Lake Turkana TEX<sub>86</sub> temperature studies carried out in different analytical facilities (Berke et al., 2012a) opted to use the calibration equation from Kim et al. (2010) for similar reasons.

### *3.4 Evaporation model parameters*

Modern evaporation was calculated using an atmospheric stability model developed by Verburg and Antenucci (2010). This model was originally designed to evaluate seasonal atmospheric stability at Lake Tanganyika using measured parameters including lake surface temperature, air temperature, relative humidity, and air pressure; all were used as inputs to calculate sensible and latent heat flux between the lake surface and the air above the lake surface as well as to quantify evaporation (Verburg and Antenucci, 2010). Verburg and Antenucci (2010) assert that large tropical lakes like Lake Tanganyika are almost always unstable; that is the air temperature just above the lake surface is always higher than the lake surface temperature (Verburg and Antenucci, 2010). Here, we assume this is also true for Lake Turkana. The modern average lake surface temperature value ( $\sim 26^{\circ}\text{C}$ ), which is approximately equal to the average TEX<sub>86</sub> value, is used as the water surface temperature input in the model. The difference between modern lake surface temperature and air temperature is  $\sim 3.5^{\circ}\text{C}$ . Modern relative humidity measurements at Lake Turkana vary between  $\sim 50\text{-}70\%$  (NOAA/NCDC, 2014). Modern wind speeds at Lake Turkana are

~10 m s<sup>-1</sup> on average (Burlando et al., 2010). The model was run three times using wind speeds of 5, 10, and 15 m s<sup>-1</sup> and relative humidity was varied between 50 and 70%. Air pressure is held constant at 1013 mbar.

## 4 Results

### 4.1 Temperature proxy results and the BIT index

The TEX<sub>86</sub> temperature record generated from Lake Turkana sediment cores varies from 24.3 °C to 28.6 °C with a mean of 25.9 °C and standard deviation of 1.1 °C (Fig. 4). There are two increases in temperature (near 27.5 °C) at ~9.2 and ~2.4 ka that exceed one standard deviation about the mean, and there are two significant increases (over 28 °C) that exceed two standard deviations about the mean, at ~11.7 and ~6.5 ka (Fig. 4), which occur near the onset and at the end of the AHP. Cooler temperatures, between 24.3 °C and 25 °C, occur between 12.7 and 12.3 ka, for short periods at 9.6 ka and 6.9 ka, for a sustained period between 5.8 and 4.5 ka, and briefly at 2.5 ka. All of the temperature decreases are near one standard deviation below the mean; none of the lowest temperatures approach two standard deviations below the mean (Fig. 4). For most of the duration of the record, the lake surface temperature fluctuates within one standard deviation of the mean on a centennial scale. The general trend of the dataset is slightly decreasing over time with an overall change of ~1.2°C.

The ratio of branched (soil-derived) to isoprenoid (aquatically-derived) tetraethers, or BIT index, is used as an evaluator of soil organic matter input (Hopmans et al., 2004) and the potential success of the TEX<sub>86</sub> paleotemperature proxy. The TEX<sub>86</sub> value is calculated using a ratio of isoprenoid tetraethers, but significant introduction of branched tetraethers

into an aquatic system suggest that terrestrially-derived isoprenoid tetraethers also influence the distributions of sedimentary isoprenoid tetraethers and the measured TEX<sub>86</sub> ratio (Hopmans et al., 2004). Accordingly, a low BIT value (<0.3) is typically required for a valid TEX<sub>86</sub> analysis. BIT values for this data set range from 0.09 to 0.25 with a mean of 0.16 and a standard deviation of 0.04. Consistently low values suggest minimal influence from soil-derived organic matter.

#### *4.2 Model results*

The model results using different wind speed and relative humidity inputs are displayed in table 2. The temperature input for each model run was 26 °C; wind speed was varied from 5 to 15 m s<sup>-1</sup> using a 5 m s<sup>-1</sup> interval. Relative humidity was varied from 50 to 70% by a 10% interval. Calculated evaporation rates vary from 750 to 7700 mm yr<sup>-1</sup> (Table 2). The evaporation rate of ~5000 mm yr<sup>-1</sup> is calculated using parameters most similar to modern conditions (wind speed of 10 ms<sup>-1</sup> and humidity of 50%). This value is much higher than the accepted value of ~2300 mm yr<sup>-1</sup> from past studies estimated from yearly lake level fall over the time period of 1945 to 1975 (Ferguson and Harbott, 1982).

## **5 Discussion**

### *5.1 Long term temperature change*

TEX<sub>86</sub> paleotemperatures indicate relative temperature stability at Lake Turkana throughout the Holocene, with a long-term average of 26 °C (Fig. 4). The full range of temperatures in the Turkana record is not unlike the range of temperatures seen in other African lakes (Table 1), and temperatures were not constant over the time period studied

(24.3 – 28.6°C). The record does not contain consistent long-term trends in temperature; however, temperature fluctuates within one standard deviation (1.1 °C) about the mean. This suggests that there was relative, long-term temperature stability during a time when there were significant shifts in other climate parameters such as precipitation and evaporation, as well as insolation, greenhouse gas concentrations, and vegetation cover.

The temperature record from Turkana shares some characteristics with records from other lakes in East Africa. Temperatures increase between 12.7 and 11.7 ka at Turkana, a characteristic that is also seen at Lake Victoria and Lake Tanganyika (Tierney et al., 2008; Berke et al., 2012a). The 4 °C temperature increase at Turkana is greater in magnitude than the change over the same time period at Lakes Victoria and Tanganyika (Tierney et al., 2008; Berke et al., 2012a). This warming is associated with deglaciation and increasing northern hemisphere summer insolation. Temperatures at Lake Turkana, Lake Victoria, Lake Tanganyika and Lake Malawi all decrease slightly between ~5.5 and 4 ka (Powers et al., 2004; Tierney et al., 2008; Berke et al., 2012a).

Lake level at Turkana was not stable during much of the Holocene, due to precipitation changes associated with AHP moisture (i.e., Owen et al., 1982; Halfman et al., 1988; Garcin et al., 2012; Morrissey and Scholz, 2014) (Fig. 4). Many of the short-term temperature changes observed in this study correlate with times of pronounced shifts in lake level, however the relationship between lake level change and temperature is not consistent. Increases in temperature correlate to both rising and falling lake level. This suggests that changes in the paleohydrology and evaporation of Lake Turkana were probably closely related to resulting temperature changes at the lake surface at times, but they do not consistently explain fluctuations seen in the temperature record.

Lake surface temperatures decreased from the early Holocene to late Holocene by 0.5 °C from a mean of 26.2 °C to 25.7 °C. This is within the error of the TEX<sub>86</sub> proxy, but follows the trend of decreasing summer insolation over the same time period (Fig. 4). While there is variation within the record, the mean value of temperatures during the AHP highstand is 0.5 °C higher than the mean value of the late Holocene lowstand temperatures (Fig. 4). By comparison of the temperature record to seasonal insolation curves, the long-term trend in the temperature record from Lake Turkana follows summer insolation (Fig. 2). The mean annual temperature at Lake Turkana is most similar to JJA and NDJ temperatures, which correspond to times of year when direct sunlight and possibly productivity are highest, potentially biasing the temperature being recorded by the TEX<sub>86</sub> record.

## *5.2 Other Turkana temperature records*

An earlier study generated a TEX<sub>86</sub> paleotemperature record from mid-late Holocene sediments from the South Basin of Lake Turkana. Berke et al. (2012a) present a TEX<sub>86</sub> temperature record from Lake Turkana that extends from ~1–6 ka, using samples from legacy 1980's sediment cores (Halfman et al., 1988, 1992) (Fig. 7) recovered from both the North and South Basin of Lake Turkana. Berke et al. (2012b) conclude that a mid-Holocene thermal maximum of 28.3 °C at 5 ka followed September-November insolation that also peaked at 5 ka. The thermal maximum indicated by Berke et al. (2012b) is not observed in the temperature record in this study. There are several explanations for different results between the two studies.

The first is a topic discussed in Berke et al. (2012b) to explain differences between temperature records generated for cores in the North and South basins of Lake Turkana. Wind mixing and upwelling in Lake Turkana create a spatially variable temperature water column cross section along the axis of the lake (Fig. 3). According to Berke et al. (2012a), the distance (~140 km) between the two cores, which were recovered from North Basin and South Basin from the previous study, is sufficient for an offset in temperature to persist over centuries. While the main cores from this study and the mid-Holocene record (LT84-2P) from Berke et al., (2012b) are both from the South Basin, they are ~15 km apart (Fig. 1). Additionally, the precise core location for LT84-2P is not known, as the cores were collected prior to the advent of the modern Global Positioning System and was located by periodic RADAR fixes and dead reckoning (Halfman, 1987). In addition to their distance, the upwelling in the South Basin (Fig. 3) is isolated to the easternmost shore, the area where all three cores from this study were recovered, while the surface circulation at the core location of LT84-2P is potentially less affected by upwelling deepwater. The differences between the two temperature records are difficult to explain as the lake is well mixed; however, lake circulation may account for some of the differences in the two records (Fig. 7).

Another possible explanation for the different results in the two studies is age model uncertainty. The material dated in Berke et al. (2012b) consisted of ostracode fractions, and core LT84-2P has only three dated samples. Other age constraints for core LT84-2P are correlated ages from other LT84 cores using marker horizons in downcore carbonate abundance and magnetic susceptibility. The age model from our study is constrained by a total of 24 radiocarbon dates from the three cores from the South Basin on material that

potentially records a more reliable age (Morrissey and Scholz, 2014). Because of the distance between LT84-2P and the cores from our study, it is not possible to correlate them stratigraphically using other proxies. Another possible explanation for differences between the two temperature records is the time elapsed between the recovery of the cores from the lake and sampling for TEX<sub>86</sub> analysis. The cores from the previous study were collected in 1984 and sampled for TEX<sub>86</sub> analysis more than two decades later, after the core was desiccated and had shrunk non-linearly by as much as ~20%. The potential for loss of precision in below-lake-floor-depth is high, and may contribute to additional offset between the two age models. All three explanations presented here together are likely responsible for differences in the records.

In figure 8, the record from LT84-2P was stretched by ~1.5 kyr to match the temperature high described in Berke et al. (2012a) with the temperature high at ~6 ka in the record from this study. It does not, however, reconcile most of the other features seen in the new temperature record. Neither the low temperatures from 5.8 ka to 4.5 nor the short-lived temperature high at 2.4 ka in the new record are replicated in the LT84-2P record (Fig. 7). The lack of correlation between these two records is best explained by differences in age models and the possibility of differential desiccation in the legacy cores from the previous study, in addition to naturally occurring variability in the temperature structure and wind mixing of Lake Turkana.

### *5.3 Ecological changes and TEX<sub>86</sub>*

The ratio of branched to isoprenoidal tetraethers, the BIT index, has been used to interpret paleoecological changes in tropical environments (Hopmans et al., 2004,

Verschuren et al., 2009; Sinninghe-Damsté et al., 2009). Branched tetraethers are mainly soil-derived, while isoprenoidal tetraethers are mainly aquatic, and increases in the ratio have been interpreted as an increase in terrestrial runoff during times of high rainfall (Verschuren et al., 2009; Sinninghe-Damsté et al., 2009). The persistent low values over the duration of the record (less than  $\sim 0.3$ ), suggest that the soil-derived component of the sediment samples is sufficiently low to permit robust TEX<sub>86</sub> temperature analysis, which is based solely on aquatic tetraethers. While there is variability in the BIT index over time, it does not contain the high-frequency variability observed in the temperature data. The correlation between BIT index and lake level change (Fig. 4) suggests that the BIT index is capturing large-scale ecological shifts within the lake basin. When lake level is stable, either high or moderately low, the BIT values from Turkana vary between  $\sim 0.1$  and 0.15 (Fig. 4). When lake level is changing or low, observed BIT are slightly elevated to values between 0.2 and 0.25 (Fig. 4).

Additionally, the influence of other sources of GDGTs over time could explain anomalous temperatures in the TEX<sub>86</sub> record (Schouten et al., 1998 2007; Blaga et al., 2009; Zhang et al., 2011). Methanotrophic archaea produce GDGTs that can influence the relative abundances of GDGTs in the ratio used in the TEX<sub>86</sub> proxy. Zhang et al. (2011) describe the Methane Index (MI) to evaluate the possible influence of methane oxidizing *Euryarchaeota* on GDGT relative abundances. Methane oxidizing *Euryarchaeota* produce GDGT-1, -2, and -3, but they do not produce crenarchaeol and its regio isomer. Thus, this index consists of the ratio of GDGT-1, -2, and -3 to GDGT-1, -2, -3, crenarchaeol and its regio isomer (Zhang et al., 2011). An MI value above  $\sim 0.3$  indicates substantial influence from methanotrophic organisms. The range of MI values from Lake Turkana samples analyzed for the TEX<sub>86</sub>

proxy is 0.14–0.32 with a mean of 0.21 and a standard deviation of 0.03 (Fig. 8). These consistently low values suggest that, in general, there was minimal influence of methanotrophic organisms at Lake Turkana over the study period. However, there is a short interval at ~4 ka that correlates to relatively high temperatures in the TEX<sub>86</sub> record that were possibly influenced by an increase in methanotrophic organisms (Fig. 8).

Another explanation for variation within the TEX<sub>86</sub> record is the presence of methanogenic archaea, which also produce GDGTs and can affect the relative abundances of GDGTs that contribute to the TEX<sub>86</sub> value (Schouten et al., 2007). The ratio of GDGT-0 to crenarchaeol (Cren) can be used to assess the influence of methanogenic organisms on the abundances of GDGTs (Schouten et al., 1998; Blaga et al., 2009). The range of GDGT-0:Cren for the Turkana record is 0.06 – 0.2 with a mean of 0.13 and a standard deviation of 0.03 (Fig. 8). All of the samples from Turkana have a ratio of 0.2 or lower, suggesting there is no other significant source for GDGT-0 other than Crenarchaeota. The high-frequency variability in the TEX<sub>86</sub> temperature record is not a product of shifts in the source of tetraethers, but rather must be a product of water column temperature variation, lake mixing and sediment preservation.

#### *5.4 High-frequency temperature variability*

The long-term temperature decrease observed in the Turkana TEX<sub>86</sub> record is overprinted with high-frequency variability. Temperatures fluctuate by ~0.5–1.5 °C on decadal to centennial timescales between 14 ka and 0.4 ka (Fig. 4). This is unlike most of the other TEX<sub>86</sub> temperature records from large African lakes, where temperatures remain relatively constant over long periods of time (Powers et al., 2005; Berke et al., 2012a; Tierney et al.,

2008). The persistent winds, mechanical heat transfer, and lake mixing are possible climatological influences on TEX<sub>86</sub> temperatures.

The temperature profile of Lake Turkana is complex due to persistent winds and substantial lake mixing (Fig. 3). Due to upwelling, the north-south temperature gradient ranges from 1–3.5 °C annually. It is broadly accepted that TEX<sub>86</sub> records the temperature of water from the upper water column (Tierney et al., 2008; Schouten et al., 2012), however the constant wave action and mixing in Turkana, particularly the South Basin, may exert an influence here. The vigorous mixing of the water column influences the distribution of tetraethers that are deposited on the lake floor. This is likely a source for variation in the temperatures that are recorded at a core location. Redox indicators from high-resolution scanning X-ray fluorescence data show significant variations between different elemental ratios (Fig. 9), and the fluctuations within these datasets correlate to fluctuations within the TEX<sub>86</sub> temperatures. The Fe:Ti and Mn:Ti ratios covary with temperature for much of the record, suggesting that preserved temperatures are related to the redox state of the lake; in this case, wind-driven mixing probably controls the redox state.

### *5.5 Short-lived temperature events and lake level change*

There are several significant, decadal and centennial scale temperature increases (over 28 °C) that exceed two standard deviations about the mean at ~11.7 and ~6.5 ka, as well as significant variations between 3 and 2.2 ka. The temperature increases at 11.7 and 6.5 ka correlate approximately to shifts in lake level associated with the onset and termination of the AHP. Fluctuations in temperature during these intervals could be related to shifts in the precipitation-evaporation ratio and the amount of cloud cover during

changing climate. Temperatures vary between 24 °C and 27 °C (Fig. 4 and 11) between 3 and 2.2 ka. This increase in temperature occurs just before a moderate lowstand that is interpreted at 2.2 ka (Morrissey and Scholz, 2014). These temperature changes may indicate a perturbation in the regional climate at this location, as they roughly correlate to slight (<1 °C) temperature decreases at ~3 ka at Lakes Tanganyika and Malawi (Powers et al., 2005; Tierney et al., 2010).

### *5.6 Regional temperature change correlations*

Climate records from large lakes in East Africa indicate that along with increased precipitation, many areas also experienced changes in temperatures during the African Humid Period (Tierney et al., 2010; Powers et al., 2005), an interval of increased northern hemisphere summer insolation (Fig. 4). In other TEX<sub>86</sub> records from East African lakes, the highest lake surface temperatures do not occur during the peak of the AHP, but are observed during the onset and during the termination of the AHP. In Lake Tanganyika (6–9 °S), temperatures as high as 28 °C occur between 11.5 and 10.7 ka and as high as 26 °C between 7 and 6.5 ka, while during the AHP temperatures ranged between 23 °C and 25 °C (Tierney et al., 2010) (Fig. 10). At Lake Malawi (10–14 °S), temperatures increased (27–28 °C) from 14–13 ka and remain over 27 °C from 6.7–4.2 ka while temperatures during the AHP were ~25 °C (Powers et al., 2005) (Fig. 10). Lake Turkana displays a similar record, with ~2 °C increases in temperatures at ~11.7 ka and ~6.5 ka, with temperatures near 26 °C (Fig. 10).

Lakes Tanganyika and Malawi are both south of the equator, and during the AHP, they both experienced summer insolation minima. Lake Tanganyika responded

hydrologically however, to peak northern hemisphere summer insolation (Tierney et al., 2008) whereas Lake Malawi did not (Powers et al., 2005). Lake Turkana is north of the equator and experienced high summer insolation during the AHP. This would suggest that lake surface temperatures should be highest at the time of peak insolation. Increased insolation, however, probably also produced a shift in the ITCZ, causing increased atmospheric convergence over the Turkana region. Increased convergence would promote increased rainfall in the area, accompanied by more cloud cover and associated increases in relative humidity. Additionally, an increase in relative humidity would limit heat loss from the lake surface from a decrease in evaporation.

#### *5.7 Modeled evaporation changes and relative humidity*

The model run using a wind speed of  $10 \text{ m s}^{-1}$  is most similar to the modern climatic and environmental conditions at Lake Turkana (Table 2). Calculated evaporation rates using modern model parameters are  $\sim 5000 \text{ mm yr}^{-1}$ . That is more than twice the amount of evaporation as the  $2300 \text{ mm yr}^{-1}$  value that is well cited in the literature (Ferguson and Harbott, 1982). Annual lake level declines recorded over several decades were used to calculate that evaporation value (Ferguson and Harbott, 1982). In the same study, workers report attempts to use a number of evaporation tank experiments and determined that abnormally high measures of evaporation were unreliable (Ferguson and Harbott, 1982). The model used here suggests extremely high evaporation may be possible under current climate conditions. Evaporation is an efficient means by which to dissipate heat from a lake system, and varying evaporation may be an explanation for the high-frequency, low-

amplitude temperature variation at Lake Turkana during a time of extreme global climate change.

Model results for paleotemperature and relative humidity proxies suggest extreme changes in evaporation (Table 2). Evaporation amounts are highly sensitive to wind speed according to model results. Wind speed at Lake Turkana today is  $\sim 10 \text{ m s}^{-1}$ , but there are no definitive proxies for ancient wind speeds. Redox sensitive elemental ratios can be used as a qualitative wind speed and degree of lake mixing, however the proxy is not precise enough to determine exact wind speed. The nightly cooling of high topography adjacent to the South Basin creates strong winds at Lake Turkana. Since the same topography persisted over the time interval of this study, the winds of today likely persisted in the past. If this is the case, then the evaporation reduction modeled during the AHP is most sensitive to the amount of relative humidity. Increases in relative humidity would be coupled with increases in precipitation and cloud cover. Past studies of Lake Turkana have reported that during infrequent thunderstorms over the lake surface, air temperature rapidly decreases, which is possibly due to a decrease in direct sunlight, as an increase in humidity should reduce heat loss from the lake surface (Ferguson and Harbott, 1982). Monthly means of measured insolation also indicate that cloud cover reduces solar insolation by up to 28% (Griffiths, 1972), which affects surface water temperature. During the AHP, evaporation decreased due to an increase in relative humidity, and temperature likely did not increase due to a decrease in direct sunlight on the lake surface. In the late Holocene, when relative humidity and cloud cover decreased, evaporation aided in the dissipation of heat that prevented an increase in surface water temperatures from increased direct sunlight.

## 6 Conclusions

- Lake surface temperatures determined from TEX<sub>86</sub> at Lake Turkana between 14 ka and 0.4 ka indicate a long-term climate trend of slightly decreasing temperature that was likely controlled by changes in summer insolation.
- Apparent increases in temperature correspond approximately to large-scale fluctuations in lake level. This may be due to increases in soil-derived tetraethers influencing the tetraether composition in the lake and biasing the tetraether distribution.
- Significant fluctuations ( $\pm 1-3$  °C) in lake surface temperature are short-lived, decade-to-century scale events imprinted over insolation-driven temperature change. The short-term events are attributed to significant lake mixing and the complex temperature profile that persists year-around at Lake Turkana.
- Lake Turkana's low elevation, near-equatorial position, arid climate, well-mixed water column, closed basin, and relatively small size are unique compared to other large African Great Lakes. The physical mixing of the water column distorts regional or high latitude climate signals in the temperature record.
- The surface water mean temperature during the late Holocene decreased by 0.5 °C as peak NH summer insolation decreased in conjunction with the termination of the AHP. This was coeval with the lowering of lake level and the onset of regional hyperaridity.
- The range of relative humidity and wind speeds present at modern Lake Turkana likely produce highly variable evaporation rates at Lake Turkana. The range of possible evaporation rates likely contributes to the high-frequency, low-amplitude

variability in the TEX<sub>86</sub> temperature record, however precise estimates on paleo-humidity and paleo-wind speeds are difficult to constrain quantitatively.

## **7 Acknowledgments**

We thank the government of Kenya for research permissions. Financial support was provided by the sponsors of the Syracuse University Lacustrine Rift Basins Research Program. We also thank the National Oil Corporation of Kenya for assistance during field operations. The authors thank the people of Loiyangalani and the Turkana Rift Valley, for their cooperation, assistance, and hospitality during multiple field seasons at Lake Turkana. We would also like to thank Dr. Shannon Loomis, Dr. Rafael Taroza, and Lily Cohen for assistance with sample preparations and laboratory procedures at Brown University. The authors would like to thank P. Verburg and J. Antenucci for the public availability of their model. We also thank Dr. Bruce Wilkinson for his comments and suggestions on early versions this manuscript.

## **Project summary**

Lakes sediments are one of the best archives of continental climate change, particularly in the tropical latitudes where continental records are otherwise poorly preserved. The Great Lakes of the East African Rift System are some of the largest and deepest lakes on Earth and contain millions of years of climate and tectonic history. Lake Turkana is the largest lake in the Eastern Branch of the East African Rift System and the largest lake in the world in a desert. It is markedly smaller, however, in length, depth, and volume compared to analogous half-graben lake basins located in the Western Branch. The Turkana region is subject to the twice annual passing of the Intertropical Convergence Zone (ITCZ) due to its near-equatorial position in northwestern Kenya. This low-elevation desert receives less than 200 mm yr<sup>-1</sup> of cumulative precipitation, and the evaporation is over 2300 mm yr<sup>-1</sup>. Wind speeds measured at Lake Turkana are upwards of 10 m s<sup>-1</sup>, which produces a well-mixed water column. This highly evaporative environment creates a hydrologically closed lake with moderately alkaline and slightly saline water.

Prior to this study, the knowledge of the sedimentary framework and paleolimnology of Lake Turkana was relatively limited. The acquisition of high-resolution compressed high intensity radar pulse (CHIRP) seismic reflection data in conjunction with ~10 m Kullenberg piston cores allowed for the recovery of a nearly 20 kyr paleolimnologic record. Sediment core lithology was described, and the cores analyzed for basic geochemical and geophysical parameters including total organic carbon, total inorganic carbon, water content, gamma ray attenuated porosity evaluation bulk density, and whole-core magnetic susceptibility. Sediment chronology is constrained by 24 radiocarbon dates from three sediment cores. Downcore density curves were used for correlation to CHIRP

seismic data, which was used to interpret seismic sequences based on stratigraphic relationships and seismic character.

With these data in hand, a multiproxy lake level history was derived for the last 20 kyr. After the Last Glacial Maximum, Lake Turkana experienced at least two desiccation events at 18.5 and 17 ka when the lake was at least 100 m lower than modern, as evidenced by basin-wide, high amplitude reflections correlated to sand intervals in the sediment cores. Lake level rose abruptly at ~11 ka as interpreted from an increase in organic carbon content and abrupt shift to silt and clay-sized sediment. It was after this shift when Lake Turkana overflowed and became part of the White Nile River System via the now relict Turkana-Nile River. Highstand conditions lasted until ~5 ka when the lake once again became a closed basin. The loss of Lake Turkana as a White Nile input likely had significant repercussions to nascent communities living along the Nile as well as the Turkana-Nile River. Lake level has remained at a moderate lowstand since its mid Holocene closure. Lake level fluctuations in this region loosely follow trends in mean solar insolation, however, onset of lake level extremes are much more abrupt than rates of insolation change.

Lake Turkana is not the only lake in East Africa with evidence for increased precipitation between ~13 and ~5 ka. This time interval is often referred to as the African Humid Period (AHP) due to the fact that many lakes were at highstand and much of the Sahara Desert was green. Increased northern hemisphere summer insolation is often invoked as a forcing for increased atmospheric convergence over much of northern Africa during this period of increased precipitation. More recently, an easterly shift of moisture derived from the Congo Basin has been proposed as an additional moisture source for

environments in East Africa during the AHP. Much of this evidence comes from an expanding number of hydrogen isotope records from different lake basins in East Africa that have allowed workers to begin to understand the zonal moisture sources in the region and how they may have changed over time.

The hydrogen isotope values of different moisture sources vary based on its transport history. The two main sources of moisture for East Africa are the Indian and Atlantic Oceans, however Lake Turkana presently receives 100% of its moisture from the Indian Ocean via the African Monsoons. Congo derived moisture is typically more depleted in deuterium than Indian Ocean moisture because it has a more complex transport history and has been subjected to more over land processes that lead to depletion. To determine the possibility of Atlantic derived moisture via the Congo Basin reaching Lake Turkana in the past, compound specific ( $C_{28}$  *n*-alkanoic acids) hydrogen isotopes ( $\delta D_{wax}$ ) were measured from the composite sediment core record from Lake Turkana.

The record revealed that hydrogen isotope values were depleted by as much as -60‰ during the AHP. Isotope depletion occurs abruptly at 13.7 ka and is sustained throughout the AHP, and values slowly become more enriched after 7 ka. This depletion suggests that Congo derived moisture had a significant influence on Turkana precipitation during the AHP, but depletion of that magnitude cannot be explained solely by a change in moisture source. An explanation for the remainder of the depletion is a significant increase in the amount effect, a fractionation process described to occur during tropical rainstorms whereas raindrops produced during thunderstorms generated by convective processes are more depleted than the moisture source. Finally, because the hydrogen isotopes were measured on leaf waxes, the vegetation type change through time must also be considered

as significant differences exist between the fractionation processes in C<sub>3</sub> vs. C<sub>4</sub> plant metabolic processes.

These three possible effects were quantified using stable carbon isotopes ( $\delta^{13}\text{C}_{\text{wax}}$ ), modern Kenyan amount effect estimations coupled with a published basin fill model, and a previously published study on the quantification of modern isotope effects caused by Congo-derived moisture for Lake Tana, a lake in the Ethiopian Highlands. It was determined that vegetation can account for up to -17‰ of the total AHP depletion, amount effect estimations range from -17‰ to -24‰ of the total depletion. After accounting for these effects, precipitation during the AHP is depleted relative to a 100% change in precipitation amount, which we suggest is driven by an influx of moisture derived from the Congo Basin. Our calculations suggest that at least 45% of the moisture supplied to this part of East Africa during the AHP was Congo-derived.

The precipitation-evaporation balance of a lake system is closely related to its heat budget. This is especially true in Lake Turkana, where evaporations rates are extremely high and precipitation changes over time have been dramatic. To attempt to quantify changes in temperature through the onset and termination of the AHP, a paleotemperature proxy originally developed for the marine system called TEX<sub>86</sub> was used to generate a 14-kyr record of lake surface temperatures for Lake Turkana. This proxy uses the relative abundance of organic compounds called Glycerol Dialkyl Glycerol Tetraethers (GDGTs) produced by temperature-sensitive aquatic bacteria (Group I crenarchaeota) that live in surface waters and are deposited on the lake floor to calculate a lake surface temperature. This proxy has recently been shown to successfully reconstruct regional and high-latitude climate events in the paleotemperatures from other large African lakes.

TEX<sub>86</sub> temperatures from 14 to 0.4 ka are highly variable and range from 24.3 °C to 28.6 °C with a mean of 25.9 °C. There is a long-term trend within the temperature record that follows mean northern hemisphere peak summer insolation. The mean temperature of 26.2 °C during the early Holocene is 0.5 °C warmer than the late Holocene mean temperature of 25.7 °C. The temperature record generated from Lake Turkana sediments, however, appears to be sensitive to lake evaporation and lake mixing processes that overprint the regional climate signal. A decade-to-century scale fluctuation of ~1 °C persists throughout most of the record. While this was an unexpected result from this analysis, it has shown that this proxy may have limitations in its application to well-mixed lake systems.

Lake Turkana has experienced dramatic climatic and limnologic changes over the past 20 kyr. The timing and magnitude of change during the African Humid Period varies between proxies, but it is clear that the landscape of Lake Turkana was affected by more humid conditions for several thousand years in the early Holocene. After the time of high rainfall, the area became hyper arid, and this environment persists to present day. Lake level has dropped ~10 m since the 1970s and continued water loss may negatively affect the hydrologic budget and water chemistry of the lake. Further concentration of ions would lead to increased salinity and alkalinity making water unsuitable for livestock watering and irrigation purposes. A negative response from fish populations would eliminate a food source for the riparian communities surrounding the lake. The future of Lake Turkana is unclear as ongoing plans to implement an 1800 MW dam on the Omo River may further deprive the lake of its main water source.

## Recommendations for future work

The results of this project provided a long-term overview of climate and limnologic change in the Turkana region, however the variability of climate on short timescales in the area is still not well understood. TEX<sub>86</sub> temperatures were highly variable on decadal to century scales, and late Holocene  $\delta D_{\text{wax}}$  values show significant variation with enhanced aridity. As today's climate continues to change, a super high-resolution, recent climate record would benefit the understanding the climate processes that occur in Lake Turkana and how they might respond to future climate change.

In conjunction with the seismic reflection data and Kullenberg sediment cores acquired for this project, several short gravity cores were collected to capture the shallowest sediments as well as the intact sediment-water interface. Sedimentation rates in these cores have been constrained by Pb-210 dating and were determined to be  $\sim 1 \text{ cm yr}^{-1}$ . A sampling strategy could be designed to generate a record of quasi-annual climate change for the past century in effort to identify the true scale of temperature and precipitation variability. High-resolution XRF scans are recommended prior to intense sampling for organic proxy analysis, as performed in this study, to evaluate changes in sediment source and distinct changes in water chemistry over time. An entire half-core sample would likely be required to acquire sufficient quantities of sediment to perform  $\delta D_{\text{wax}}$ ,  $\delta^{13}\text{C}_{\text{wax}}$ , and TEX<sub>86</sub> analysis.

If sediment could be collected on an interannual basis, these proxies could be applied on the interannual scale to assess true seasonal climate variability. Seasonal sediment trap studies could further enhance the understanding of annual variability in the regional climate system. However, this would require additional fieldwork. The potential

success of long-term sediment trap studies in Lake Turkana is questionable due to the deep wave base of the lake. An additional approach to determining annual variability is analysis of satellite photos and other remote sensing data to quantify changes in wind patterns on the lake surface as well as seasonal changes in vegetation cover.

Finally, a specific issue that was encountered in this project was the quantitative analysis of the amount effect at Lake Turkana. The quantification of precipitation on a per-event scale coupled with isotope measurements of water from the same events would greatly enhance the understanding of the amount effect in the region today. These data simply do not exist at present, and assumptions must be made when extrapolating these data from other regions. The acquisition of these data would also lend additional insight into the different fractionation components of the  $\delta D_{\text{wax}}$  record analyzed in this study.

## **Biographical Data**

*Name of Author:* Amy Jo Morrissey

*Place of Birth:* Branson, Missouri

*Date of Birth:* September 22, 1986

*Undergraduate schools attended:*

- University of Missouri, Columbia, Missouri

*Degrees awarded:*

- Bachelor of Science, 2009, Geological Sciences, *magna cum laude*, with honors in
- Bachelor of Arts, 2009, Anthropology, *magna cum laude*

*Professional experience:*

- Teaching and research assistant, Department of Earth Sciences, Syracuse University, 2009–2014
- Geologist Intern, Newfield Exploration Company, Houston, Texas, 2009
- Science Peer Tutor, Success Center, University of Missouri 2008–2009
